2961

SLEEP.—This term is employed to designate that state of suspension of the sensory and motor functions, which appears to alternate, in all animals, with the active condition of those functions, and which may be made to give place to it by the agency of appropriate impressions upon the sensory nerves.

Although this may seem a complex definition of a state which seems to be in itself so simple, yet it will not be found easy to alter its character without rendering it less stringent. We more especially desire to exclude from it the abnormal condition of *coma*, in all its forms; whether resulting from the influence of pressure or effusion within the cranium, or consequent upon the poisoning of the blood by narcotic substances, or occurring as part of that inexplicable series of phenomena which are termed hysterical. The state of coma, where not so intense as to affect the movements of respiration and deglutition, is identical with profound sleep as regards its obvious manifestations; but there is this important difference, that simple sleep may be made to give place to activity by the application of appropriate stimuli to the sensorial system; whilst in complete coma, no impressions on the sensory nerves have any power of bringing back the consciousness. Between these two conditions, however, every gradation may be seen; as in the heavy sleep produced by an over-dose of a narcotic, in incomplete hysteric coma, or in the torpor resulting from slow effusion within the cranium.

The necessity for sleep seems to arise from the fact, that the exercise of the animal functions is in itself destructive of the substance of the organs which minister to them; so that, if the waste or disintegration produced by their activity be not duly repaired, they speedily become incapacitated for further use. This doctrine is now so generally admitted, that it does not seem requisite to adduce proofs in its support. The substance of muscles is regenerated during the suspension of their action in simple repose; and it is not essential that, for this purpose, a state of unconsciousness should intervene. As the substance of the nervous centres and trunks, more especially the former, undergoes a similar disintegration as a necessary consequence of its activity, this too requires a period of repose for its regeneration; but the repose, or suspension of functional activity, of the sensorial portion of the nervous system, necessarily involves unconsciousness; and it appears to be on the *nutritive regeneration* which takes place during true sleep, that its *refreshing* power depends. No such refreshment is experienced from the unconsciousness of coma, however prolonged; and there are some forms of ordinary slumber in which it is more or less deficient. The organic functions are not affected in any considerable degree by the suspension of the sensorial; for we find that not only are the operations in which these functions *essentially* consist uninterruptedly carried on, but that the muscles, nerves, and nervous centres also which are concerned in maintaining them, are enabled to sustain an unintermitted action. Thus the movements of the heart are not, in warm-blooded animals at least, normally suspended, from the first development of that organ until the close of life; the respiratory motions, in like manner, are kept up uninterruptedly from birth to death; and the propulsion of food along the alimentary canal during sleep by the peristaltic contraction of its muscular coat, the sustained action of the sphincters, the peculiar position of the eyes, and the active state of the extensor muscles of the legs in animals which sleep standing, are additional evidences that the state of continuous repose is not required for the renovation of the powers of certain parts of the nervous and muscular apparatus. To use Dr. Marshall Hall's phraseology, "the true spinal system never sleeps;" and, whatever we may think of the existence of his "true spinal" system of nerve-fibres, as distinct from those which minister to the functions of the encephalon, there can be no longer any doubt that the ganglionic portion of the spinal cord is a distinct centre of nervous action, which retains its power of actively responding to impressions made upon it, during the profoundest repose of the other centres; whilst, from the complete suspension of its functions, even for a very brief period, death inevitably results.

In following out our inquiry into the nature of sleep, and of certain conditions allied to it, we shall find it convenient to regard the encephalon as composed of four leading or primary divisions: 1. The *medulla oblongata*, which essentially consists of a prolongation of the spinal cord, including the centres of respiration and deglutition; and also having incorporated with it, without properly forming part of it, the ganglia of hearing and of taste; 2. The *ganglia of sensation*, including, with the olfactive, optic, auditory, and gustative centres, the corpora striata and thalami optici, which are probably, when taken together, to be regarded as the ganglia of tactile sensation*: 3. The *hemispheric ganglia* (Solly), or peripheral portion of the *cerebral hemispheres:* and 4. The *cerebellum.*

The *first* of these divisions really belongs to the spinal cord, and, like it, is constantly active.—The *second* appears collectively to form the true *sensorium*, to which external impressions must be conveyed, in order that they may be *felt* (each class of sensations being received through the medium of its own ganglion), and from which proceeds the stimulus to those automatic movements which can only be excited by a sensation. Such are the truly *instinctive* actions.—The *third* division, of which scarcely a rudiment exists in the lowest fishes, although it constitutes by far the largest proportion of the encephalon in man, seems to be the instrument through which *ideas* are generated, by which they are retained and made the subjects of intellectual

* See British and Foreign Medical Review, vol. xxii. p. 510.

processes, and by which voluntary determinations are formed. Impressions made upon the organs of sense would seem only able to act on the hemispheric ganglia through the medium of the sensorium; whilst the voluntary determinations, resulting from the exercise of the reasoning powers, can only act on the muscular system by the transmission of a downward impulse from the hemispheric ganglia to the automatic centres, in which the motor nerves originate.

If this be a true representation, the ordinary phenomena of sleep are not difficult of comprehension. The state consists essentially in suspended activity of the *sensorium*, so that impressions made on the organs of sense are neither *felt* nor *perceived*,—that is, neither excite sensations, nor give rise to ideas. In like manner, those automatic movements which are dependent upon sensations for their excitement are suspended; and as the torpor of the sensorium cuts off the functional connection between the hemispheric ganglia and the muscles, the latter cannot be called into activity by any mental operations in which the former may be concerned. In ordinary profound sleep, the hemispheric ganglia would seem to be in the same passive condition as the sensorium itself; so that *all* mental activity is suspended. In dreaming, however, there is a train of ideas, called up by the laws of association, and not regulated by any voluntary control, bespeaking a partial activity of the hemispheric ganglia. Into the conditions of this phenomenon we shall inquire hereafter; at present only observing, that if the sleep be deep, external impressions are as completely unperceived by the dreamer, as they are in a state of entire unconsciousness; and that, in like manner, the strongest desire felt by the dreamer to perform certain bodily movements, even when he fancies that his life depends upon them, is as ineffectual as if he were suffering from a total paralysis. If external impressions are in any degree felt by the dreamer, or his volition can exert its power over the movements of his body, the sleep is not profound, but rather approximates towards the state of somnambulism or sleep-waking, in which the sensorial as well as the hemispheric ganglia are in a condition of partial activity.

The state of simple sleep, again, is allied to that of hibernation (*see* HIBERNATION); the difference between them being essentially this, that in the latter condition, besides the profound torpor of the sensorial centres, there is a great diminution or complete suspension of the activity of the organic functions. We may trace, in fact, every gradation between the simple repose of the sensorial centres, in which the state of sleep essentially consists, to that complete suspension of all the functions of life, which is of ordinary occurrence, during the winter season, in cold-blooded animals. Many of these can even endure the freezing process without the loss of their vitality; their activity being restored by the renewal of warmth. Next to this is the condition of those hibernating mammalia, which pass the winter in a state of uninterrupted torpor, and in which the organic functions seem reduced to their lowest possible amount of activity, short of entire stagnation. This reduction is manifested in the slowness of the circulation, the infrequency of the respiratory movements, the low degree of heat sustained, the abatement of the demand for food, and the small amount of carbonic acid, urea, and other excretory products, set free during the persistence of the hibernating state. But there are other hibernating mammals, in which the reduction is less decided, and the torpor less profound; these animals awaking from their repose at long intervals, taking food from the store which they have prepared, and again relapsing into inactivity. And there are others, again, in which it differs but little from ordinary profound sleep, except that the proportion of time passed in the waking state is much less than usual. Further, it is a curious observation of Dr. M. Hall's (loc. cit.), that the ordinary diurnal sleep of certain hibernating mammalia presents, in the reduced activity of the organic functions, an approach to the torpor of their winter state.

Sleep of Plants.—The complete suspension of the *organic* as well as of the *animal* functions during the hibernation of cold-blooded animals corresponds with what has been termed the *winter sleep* of plants. But plants have also what has been called a *diurnal sleep;* and although it is obvious that plants can present no phenomena really analogous to those in which we have defined the sleep of animals to consist, yet there are periodical changes in the condition of their leaves and flowers which are deserving of consideration under this head, especially as affording ing an additional indication that even in the functions of organic life there is a tendency to a more or less decided alternation of activity and quiescence. The parts of plants which exhibit the changes in question, are the *leaves* and the *flowers*. In the former we frequently notice an entire difference in the nocturnal and diurnal aspects of the leaves, which is the result of a periodic change, affecting either the position of the leaf as a whole, or that of the several leaflets of which a compound leaf is formed. The petioles, or stalks of the leaves or leaflets, either bend upwards or downwards; so that the flattened surface of the leaf is either elevated or depressed. This is not a result of simple flaccidity; for, as De Candolle remarks *, the nocturnal position is maintained with the same rigidity and constancy as the diurnal; so that the "sleeping" leaf would be broken, more readily than it could be forced into the position which is proper to it during the day. Eleven different modifications are enumerated by the distinguished botanist just cited, in the manner in which the leaves incline themselves to the stalks on which they grow. Thus, of the entire leaves which exhibit this phenomenon, some sleep face to face, others back to back,

* Physiologie Végétale, p. 855.

others fold in at the sides so as to embrace the stem or to protect the flower which arises from their axil. It is rare to see a movement of the whole of a compound leaf, when its individual portions fold together; such a movement is seen, however, in the *Mimosæ*. The variety of positions assumed in sleep by the subdivisions of compound leaves is very considerable, and need not be here enumerated: the phenomenon is best exhibited by the *Leguminosæ* and the *Oxalideæ*.

Of the causes of this phenomenon, little can be definitely stated. They are not to be looked for solely in the operation of external physical agents, such as light, heat, and moisture; for it can be easily shown that the changes in question cannot be thus accounted for, without attributing to the plants by which it is exhibited a tendency to such periodical manifestations inherent in their own constitution. Thus, when sensitive plants are confined in a dark room, their leaflets periodically fold and open as usual; the periods, however, being somewhat lengthened. On the other hand, when exposed to continued light, the periodical folding and unfolding still occurs, but the periods are shortened. And when the plants are exposed to strong lamplight by night, and excluded from all light by day, their periods of sleep become extremely irregular for a time, but in the end the plants generally close their leaves during the day and open them at night. No such modifications can be induced, however, in the *Oxalideæ;* their periods of opening and closing their leaves being unaltered by light, darkness, or by the disturbance of the natural sequence of the two. In the same manner it may be proved that these movements cannot be laid to the account of changes of temperature; for it appears from the experiments of De Candolle, that they continue to take place in plants exposed to various degrees of temperature, as well as in those left in air, provided that the heat or cold be not sufficient to injure the health of the plants. And by the same method of exclusion, they can be shown not to be dependent upon variations in the amount of circumambient moisture; since they continue equally well, *cæteris paribus*, when plants are kept in stoves the humidity of whose atmosphere is uniform, and in some cases even when the plants are entirely immersed in water. We must conclude, then, that although the exact time of the occurrence of the phenomenon may be liable to modification from the influence of external agents, its performance is essentially independent of them, aud must be referred to causes inherent in the plant itself.

The periodical closing of *flowers* is a change which is obviously analogous to the sleep of leaves. Many flowers only expand themselves once, and speedily wither. Even in this case, however, there is often considerable regularity in the time of expansion, indicating periodicity. But in the flowers which remain fresh for some days, some degree of alternation between closure and expansion may be generally discerned. There is no definite relation, however, between the sleep of flowers and that of leaves; for they may be united in the same individuals, or be exhibited separately in different species of the same genus. Among other curious examples which show the absence of connection between the two classes of phenomena, is one cited by De Candolle from Berthollet; the subject of it being an Acacia cultivated in the garden at Orotava, in which the leaves closed at sunset, but the flowers then expanded, their numerous stamens raising themselves up like tufts of feathers, so as to become conspicuous; whilst in the morning, when the leaflets assumed their diurnal position, the filaments relaxed so that the bunches of stamens gave to the flowers the appearance of floss-silk, and the flowers themselves partly closed together.

It has been ascertained by Meyen, that, by the action of artificial light and darkness, the usual hours for opening and closing may be changed in flowers as well as in leaves. Thus he found that after passing two days in a room from which external light was excluded, but which was lighted by four Argand lamps, the flowers of *Ipomœa purpurea*, which naturally open during the night, expanded in the morning; whilst those of *Oxalis tetraphylla*, at the end of the fourth day of artificial illumination, opened in the evening, instead of at their usual morning hour.

Periodicity of Sleep. — There can be little doubt that a tendency to occasional repose is inherent in the constitution of every animal possessed of a sensorial apparatus; and that this disposition is so arranged as to correspond in its periodical recurrence with the diurnal revolution of the earth. Although we are accustomed to think that "night is the time for sleep," and although, in our own case and in that of most other animals, darkness and silence favour repose, yet it must be borne in mind that there are many tribes of animals whose period of activity is the very same with that during which most others are wrapped in slumber. Thus, among lepidopterous insects, we find the activity of the greater part of the butterflies to be diurnal, that of the sphinges to be crepuscular, and that of the moths to be nocturnal. So among the insectivorous birds, we find the diurnal swallow replaced during the night by the goatsucker (or night-jar); whilst the insectivorous bats are most active during twilight. Among the raptorial birds, again, we find the whole tribe of owls, with only one or two exceptions, to be either nocturnal or crepuscular in their activity. And among carnivorous animals we meet with a similar diversity. As a general rule, the vegetable-feeders of all tribes are diurnal in their activity, taking their repose at night. The nocturnal predaceous animals take their repose during the day; and those whose period of activity is the twilight, sleep partly by night and partly by day.

Notwithstanding this variety as to the periods of sleep and activity, the complete cycle in every case is fulfilled in twenty-four hours; and this uniformity in their recurrence would seem to indicate either an *entire* and invariable dependence on external agencies, or else a periodical tendency to sleep, inherent in the animal kingdom, and corresponding with the cycle of day and night. The experience of the human species seems to be decisive in favour of the latter view.

There is, among all tribes of mankind, a general uniformity in the periods of slumber and activity, which is scarcely inferior to that observable among the lower animals; yet we find reason to believe that this periodicity is a law of our own organic constitution, for it is quite certain that it cannot be seriously departed from without injury to the system, and that, even where light and warmth are continuous through the whole range of the twenty-four hours (as during the summer in arctic regions), the same periodical desire for sleep manifests itself, resistance to which is prejudicial to the health. As Dr. Whewell justly remarks* — "No one can doubt that the inclination to food and sleep is periodical, or can maintain, with any plausibility, that the period may be lengthened or shortened without limit. We may be tolerably certain that a constantly-recurring period of forty-eight hours would be too long for one day of employment and one period of sleep, with our present faculties; and all whose bodies and minds are tolerably active will probably agree, that, independently of habit, a perpetual alternation of eight hours up and four in bed would employ the human powers less advantageously and agreeably than an alternation of sixteen and eight." We may remark, however, that when the habit has been once acquired, the *shortening* of the cycle is probably not so injurious as its *extension*. We know by experience that the habitual attempt to sustain an uninterrupted activity during more than sixteen or eighteen hours at a time, is either unsuccessful, or, if successful, is very wearing to the system. On the other hand, the experience of seamen who kept "watch and watch" during long voyages without any obvious injury to their health, indicates that if the due amount of sleep be obtained within every twenty-four hours, the division of the cycle is not attended with any prejudicial effect. On the whole, we may conclude with Dr. Whewell, that, "when we have subtracted from the daily cycle of the employments of men and animals, that which is to be set down to the account of habits acquired, and that which is occasioned by extraneous causes, there still remains a periodical character, and a period of a certain length, which coincides with, or at any rate easily accommodates itself to, the duration of the earth's revolution.

Causes of Sleep. — The most potent of all the causes of sleep, which is capable of acting by itself, when in sufficient intensity, in opposition to the most powerful influences tending to the continuance of wakefulness, is the condition of the nervous system induced by its protracted functional activity. Sleep may thus come on in the midst of the roar of cannon, and this not merely in persons accustomed to the noise, but in those who have never previously experienced it. Thus it is on record that during the heat of the battle of the Nile, some of the boys who were over-fatigued fell asleep on the deck. We have known a listener to an orchestral performance drop off in slumber during the noisiest part of the grand finale. Again, the continued demand for muscular activity is not incompatible with the access of sleep. During fatiguing marches, as in the retreat to Corunna, it has been repeatedly noticed that whole battalions of infantry have slumbered whilst in motion; muleteers frequently sleep on their mules, coachmen on their boxes, and post-boys on their horses; and factory children, before the shortening of the hours of work, were often known to fall asleep whilst attending to their machines. Bodily pain, again, yields before the imperative demand occasioned by the continued exhaustion of the powers of the sensorial centres. Of this the medical practitioner has frequent illustrations. It is well known, too, that the North American Indians, when at the stake of torture, will go to sleep on the least remission of agony, and will slumber until the fire is applied to awaken them. It is related that Damiens slept during his protracted tortures upon the rack; and that this having been prevented by the constant renewal of fresh torments, he spoke of the want of sleep, a little before the termination of his existence, as the most dreadful of all the sufferings he had endured. That the strongest voluntary determination to remain awake is forced to give way to the demand for sleep produced by the exhaustion of nervous power, must be within the experience of every one.

It does not appear to be of any consequence whether this exhaustion is produced by the active exercise of volition, emotion, reflection, or simple sensation. In all alike the sensorial centres must participate; by all alike, therefore, must their nervous substance be subjected to that disintegration which cannot proceed beyond a certain point without either being repaired by sleep, or producing a state of exhaustion which becomes fatal. Nevertheless, we find that the involuntary continuance of mental activity is unfavourable to access of sleep, so as to oppose the action of other predisposing influences; and such persistence will be found to be especially difficult to check in cases in which the *feelings* are concerned. The activity of the purely *intellectual* operations, which can be suspended at any moment, provided the feelings be not interested in their continuance, predisposes to sleep instead of preventing it. But the *desire* to work out a result, or to complete the survey of a subject, is an *emotional* state which induces restlessness, remaining active until it is gratified. So, again, anxiety or distress is a most frequent cause of wakefulness; the ex-

* Bridgewater Treatise, p. 40.

citement of the feelings keeping up a *forced* state of mental activity, which no voluntary effort can subdue. The state of *suspense* is in most persons more difficult to bear with equanimity, and is more opposed to the access of sleep, by the continual perturbation which it induces, than the greatest joy or the direst calamity when certainty has been attained. Thus it is a common observation that criminals under sentence of death sleep badly so long as they entertain any hopes of a reprieve; but as soon as they are satisfied that their sentence will be certainly carried into execution, they usually sleep more soundly,—and this even on the very last night of their lives. That the continued excitement of the feelings, whilst producing an indisposition to sleep, really occasions as great a demand for it in the system as is produced by the most active exercise of the intellectual powers, is evident from the very exhausting effects of its protraction; which necessitate a long period of tranquillity for restoration to health.

Among the most powerful of the predisposing causes to sleep, is the *absence* of sensorial impressions: thus darkness and silence usually conduce to repose; and the cessation of the sense of muscular effort, which takes place when we assume a position that is sustained without it, frequently acts as the complement of all other influences. There are cases, however, in which the continuance of an accustomed sound is necessary instead of positive silence, the cessation of the sound being a complete preventive of sleep. Thus it happens that persons living in the neighbourhood of the noisiest mills or forges cannot sleep elsewhere; and when, to induce repose in illness, the mill or the forge has been stopped, the cessation of the sound only occasions more obstinate wakefulness. Such instances, perhaps, fall within the next category of predisposing causes,—namely the *monotonous repetition* of sensorial impressions. Every one knows how efficacious a provocative of sleep is the droning voice of a heavy reader, especially when his subject is equally prosaic. The ripple of the calm ocean upon the shore, the murmur of a rivulet, the sound of a distant waterfall, the rustling of foliage, the hum of bees, and similar monotonous impressions upon the auditory sense, are usually found to induce sleep; and Boerhaave relates, that being desirous of procuring sleep for one of his patients troubled with obstinate insomnia, he directed a brass pan to be so placed as to receive a succession of drops of water, the sound of which had the desired effect. A lulling influence, however, is not universally thus produced; for we have known a case in which sleep was altogether kept away by the sound of dropping water, which seems to have occasioned a state of emotional excitement. Not only is the repetition of auditory impressions provocative of sleep; uniform succession of gentle movements has a similar effect upon the sensorium through the sense of vision. The sleep thus induced, however, is usually characterised by certain peculiarities which will be described hereafter.—The recurrence of impressions received through the sense of touch has the same effect. Thus Dr. Elliotson says*,—"I know a lady who often remains awake in spite of every thing, till her husband very gently rubs her foot; and by asserting to a patient my conviction that the secret of an advertising *hypnologist* whom I allowed to try his art upon the sleepless individual, and which he did for a time successfully, was to make him gently rub some part of his body till he slept, he confessed this to be the fact." The rocking of the infant's cradle, or the gentle swaying of the body backwards and forwards in the arms, are predisposing causes of sleep well known to nurses.

In these and similar cases, the influence of the impressions would seem to be exerted in withdrawing the mind from the consciousness of its own operations, the loss of which, as we shall presently point out, is the transition-step of the passage into complete unconsciousness. The reading of a dull book acts in the same mode. There is a monotony of sensorial impressions, the eyes wandering on from line to line and from page to page, without any mental interest in the sensations received; and if the voluntary effort of attention be intermitted, the thoughts pass off along their own spontaneous train, whilst the sensorial centres are left free to the soporific influence of monotony.

The foregoing are the chief causes of sleep, which operate directly through the sensorial organs themselves. We have now to consider those whose action is indirect, being exerted primarily on the organic functions. Of these the first in order of importance are those which produce increased *pressure* of blood within the vessels of the encephalon. Thus the assumption of the recumbent position operates in this method as a powerful predisponent to sleep, as well as by rendering all muscular effort unnecessary for the maintenance of the position of the body. To this cause again we are probably to attribute, in great part at least, the drowsiness which succeeds a full meal, the pressure within the encephalic vessels being increased by the pressure of the distended stomach upon the vessels of the abdomen; but the circulation of imperfectly assimilated matter in the blood may possibly concur in the production of the result. The influence of pressure is most characteristically seen in cases of gradual effusion of blood or of serum from the vessels of the brain: this at first occasions a state of sopor but little different from profound ordinary sleep; but with the increase of the effusion there is an increase in the depth of the slumber; the patient can no longer be aroused by sensorial impressions which were at first sufficient to re-excite consciousness, and at last complete coma comes on.† A

* Physiology, p. 609.

† Dr. Marshall Hall has advanced the hypothesis, that *ordinary sleep* is the result of congestion of the brain produced by compression of "certain veins,"

moderate degree of warmth favours sleep; perhaps by increasing the energy of the heart's contractions, at the same time that the walls of the vessels are more relaxed than usual, and thus yield to the impulse. A moderate degree of cold usually has the opposite effect, more especially when the cold is sufficient to produce uneasy sensations. But cold of great severity produces drowsiness, sopor, and even complete coma; apparently by producing a contracted state of the superficial vessels of the body, and thus occasioning an increase of sanguineous pressure on the encephalic centres. Again, the circulation of blood charged with narcotic substances through the brain, is one of the most powerful of all hypnotising agencies; and this, again, may produce every gradation of effect, between simple sleep, from which the patient may be easily aroused, and the profoundest coma. One of the most common instances of the operation of this cause, is the production of drowsiness by a deficiency of ventilation; the carbonic acid which accumulates in the blood, when not freely carried off in the air, having the properties of a powerful narcotic.

Phenomena of ordinary Sleep.— The state of perfect sleep is characterised by negative rather than by positive phenomena. As already stated, it essentially consists in the complete suspension of the sensorial powers, and of all those movements in which the nervous system participates, except the simply reflex: with this is conjoined a partial or complete suspension of the functional activity of the cerebrum. According to the more or less potent operation of the soporific causes, will be the degree of insensibility to impressions upon the afferent nerves. No ordinary cause, as we have already shown, is so powerful as previous fatigue. Of the profoundness of the sleep which may result from it, — in combination, perhaps, with two other agents, warmth, and an atmosphere somewhat charged with carbonic acid, — the following remarkable example may be cited from the "Journal of a Naturalist." It may be proper to mention that, the correctness of the statement having been called in question, it was fully confirmed by Mr. Richard Smith, the late senior surgeon of the Bristol Infirmary, under whose care the sufferer had been. "A travelling man, one winter's evening, laid himself down upon the platform of a lime-kiln, placing his feet, probably numbed with cold, upon the heap of stones, newly put on to burn through the night. Sleep overcame him in this situation; the fire gradually rising and increasing, until it ignited the stones upon which his feet were placed. Lulled by the warmth, the man slept on; the fire increased until it burned one foot (which probably was extended over a vent-hole) and part of the leg above the ancle entirely off, consuming that part so effectually, that a cinder-like fragment was alone remaining,—and still the wretch slept on! and in this state was found by the kiln-man in the morning. Insensible to any pain, and ignorant of his misfortune, he attempted to rise and pursue his journey, but missing his shoe requested to have it found; and when he was raised, putting his burnt limb to the ground to support his body, the extremity of his tibia crumbled into fragments, having been calcined into lime. Still he expressed no sense of pain, and probably experienced none, from the gradual operation of the fire, and his own torpidity during the hours his foot was consuming. This poor drover survived his misfortunes in the hospital about a fortnight; but the fire having extended to other parts of his body, recovery was hopeless." It may be added that cases are recorded by medico-legal writers, in which defloration of a virgin, followed by conception, has been effected whilst she was in a state of ordinary sleep, rendered unusually profound by previous fatigue; but such statements are obviously liable to considerable doubt, and scarcely appear entitled to credence.

Besides the suspension of the sensorial functions, however, there is usually a slight diminution in the activity of the functions of organic life. The heart's contractions are less frequent, but the pulse is fuller. So likewise the respiratory movements are diminished in number; but the inspirations are deeper. Less carbonic acid is produced than during a similar bodily inactivity in the waking state. As might be expected from these differences, the amount of heat generated in the body is diminished, and there is much less power of resisting the effects of cold. So remarkable is this abatement, that when the body is exposed to intense cold (as in the well-known attempt of Sir Joseph Banks and Dr. Solander to explore Terra del Fuego), "to sleep is to die." There would seem, too, to be a diminution in the power of resisting other morbific agencies. Thus all authorities agree that *sleeping* in a malarious atmosphere is much more liable to engender the diseases produced by it, than spending the same length of time in the same place, but in the waking state. As a general rule, it would seem that the secreting processes go on with diminished activity during sleep; but to this the cutaneous transpiration is an exception, so that, in debilitated states of the system, a profuse sweating often occurs as soon as the patient falls asleep. From this diminished activity of the organic functions it happens that hunger is not renewed so speedily after sleep as when the same number of hours have been passed in watching; a fact well known to those who are liable to suffer habitually or occasionally from the want of food. In this

---

by "a state of contraction of certain muscles of the neck." (See his Observations in Medicine, second series, p. 27.) He does not, however, offer the least proof of this hypothesis, nor does he even name the muscles or veins to which he refers. We presume that the platysma myoides and the external jugular are meant. If so, why should not a slight compression of the vein by any other means have the effect of producing sleep at will?

respect, then, even the ordinary sleep of the warm-blooded animal may be regarded as an incipient hybernation. Some writers have spoken of the organic functions as performed with *increased* activity during sleep; a doctrine so inconsistent with obvious facts, that it could never have been sustained except on the basis of a preconceived idea with regard to the antagonism between the relative activity of the functions of organic and animal life, which idea is in itself fallacious. The actual renovation of the nervous and muscular tissues by the nutritive processes, probably takes place with peculiar energy during the functional inactivity of those parts; but the preparation of the nutritive materials, which is the office of the digestive and assimilative apparatus, seems to go on more slowly during sleep; and it is quite certain that less oxygen is then taken into the system, and less carbonic acid generated and set free.

The *access* of sleep is sometimes quite sudden; the individual passing at once from a state of mental activity to one of complete torpor. More generally, however, it is gradual; and is marked by phenomena which are particularly worthy of attention. "While the mind remains poised, as it were, between sleep and the opposite condition," says Dr. Macnish*, "it is pervaded by a strange confusion, which almost amounts to wild delirium; the ideas dissolve their connection from it, one by one; those which remain longest behind are faint, visionary, and indistinct; and its own essence becomes so vague and diluted, that it melts away in the nothingness of slumber; as the morning vapours are blended with the surrounding air by the solar heat." In this passage there is an attempt made to depict the result of the loss of that power of voluntary control over the current of thought, the possession of which is the especial characteristic of the human mind in its state of normal activity. It is the complete suspension of this power, as we shall presently see, which, taken in connection with the entire want of sensibility to external objects, constitutes the state of dreaming; and the same suspension, occurring before the mind is altogether withdrawn from connection with the external world, constitutes that curious intermediate state betwixt sleeping and waking, which may readily pass into either condition. Thus, if the torpor of the sensorial centres be allowed to increase, sleep is produced; but if it be dissipated by some sensory impression of unusual strength, wakefulness is brought back again, a dreamy impression remaining, both of what had been passing in the mind itself, and of that which had been taking place around. Now, it appears to be by suspending the mind's attention to its own proceedings, and by drawing off the attention of the sensorium from all other impressions upon the organs of sense, that the monotonous sensations already referred to favour the access of sleep. And it may be further affirmed that all the successful plans for voluntarily producing sleep have some such *modus operandi*; their success being dependent upon the intentional fixation of the thoughts upon some one class of sensory impressions (as in the method of Mr. Gardner), or upon some very simple and uniform mental process (such as counting, repeating a French or Greek verb, &c.); and when the attention has been once thus fixed, the monotony of the impression serves to retain it there, so that it abandons, as it were, all control over its operations, and allows itself to be gradually wrapped in repose under the influence of that continued recurrence of similar impressions, which seems even more potent as a soporific than the suspension of *all* sensational stimuli.

The gradual loss of consciousness and of voluntary control over the muscular system during the invasion of sleep is thus described by Dr. Macnish:—"Previous to the accession of sleep, a feeling of universal lassitude prevails; this sensation heralds in the phenomena of slumber, and exhibits itself in yawning, heaviness of the eyes, indifference to surrounding objects, and all the characteristics of fatigue. If the person be seated, his head nods and droops, and, in all cases, the muscles become relaxed, and the limbs thrown into that state most favourable for complete muscular inaction. The lying position is, consequently, the best adapted for sleep, and the one which is intuitively adopted for the purpose. The organs of the senses do not relapse into simultaneous repose, but suspend their respective functions gradually and successively; sight, taste, smell, hearing, and touch, parting with sensation in the order in which they here stand, and gliding insensibly away. In the same manner the muscles do not become simultaneously relaxed; those of the limbs giving way first, then those of the neck, and lastly the muscles of the spine. Nor do the external senses, on awaking, recover all at once their usual vigour; we, for some seconds, neither hear, nor see, nor smell, nor taste, nor touch, with our usual acuteness. Ordinary sights dazzle our eyes; ordinary sounds confuse our ears; ordinary odours, tastes, and sensations, our nose, our tongue, and our touch: they awake successively, one after another, and not in the same instant." *

The power of being *aroused* by impressions made upon the organs of sense, is, as already remarked, one of the chief distinctions between *sleep* and *stupor*. The strength of the impression requisite to produce this effect depends upon two circumstances, which require separate consideration: first, the profoundness of the slumber; and, second, the relation of the impression to the habitual condition of the mind. It is a familiar fact that most persons are much more easily aroused towards the morning, when the slumbers are lighter, than they are during the early part of the night, when the sleep is more profound. In fact, the spontaneous awakening which takes place when our repose has been sufficient for the restoration of mental

* Philosophy of Sleep, p. 21.

* Op. cit. p. 22.

vigour, may generally be traced to some sensory impression of a trivial nature, such as the striking of a clock, which would have produced no effect at a previous time. Some persons, however, always sleep so heavily, that they require a strong impression to arouse them, even when they have had an ample allowance of repose. It is through the hearing and the touch that the awakening impressions are ordinarily conveyed; but either of the other senses may serve as their channel. Thus, although the closure of the eyelids destroys the acuteness of the perception of light, the eyelids are sufficiently transparent to allow of an impression being made by a light of moderate intensity; so that those who sleep in a room whose window has an eastern aspect, and is not furnished with sufficient means of excluding the sun's rays, are liable to be aroused by their ingress some time before the natural amount of repose has been taken. So, again, the sleeper may be awakened by unusual odours; thus the inmates of a burning house are sometimes first aroused by the smell of fire. The introduction of substances possessing a strong taste into the mouth, will also usually put an end to the state of slumber; but when the slumber is very profound, such substances may be received, and even swallowed, without the sleeper being thereby awakened.

The variety of modes in which the operation of sensory impressions on the sleeper is modified by the previous habitual state of mind, is one of the most remarkable points of the whole subject. The general rule is, that habitual impressions of any kind have much less effect in arousing the slumberer, than those of a new or unaccustomed character. An amusing instance of this kind has been related to the author, which, even if not literally true, serves extremely well as an illustration of what is unquestionably the ordinary fact. A gentleman who had taken his passage on board a ship of war, was aroused on the first morning by the report of the morning gun, which chanced to be fired just above his berth; the shock was so violent, as to cause him to jump out of bed. On the second morning he was again awoke, but this time he merely started and sat up in bed; on the third morning the report had simply the effect of causing him to open his eyes for a moment, and turn in his bed: on the fourth morning it ceased to affect him at all, and his slumbers continued to be undisturbed by the report as long as he remained on board. It often happens that sleep is terminated by the *cessation* of an accustomed sound, especially if this be one whose monotony or continuous repetition had been the original inducement to repose. Thus, a person who has been read or preached to sleep, will awake, if his slumber be not very profound, on the cessation of the voice; and a naval officer, sleeping beneath the measured tread of the watch on deck, will awake if that tread be suspended. In this latter case, the influence of the simple cessation of the impression will be augmented by the circumstance next to be alluded to, which has received too little attention from writers on this subject, but which is of peculiar interest both in a physiological and psychological point of view, and is practically familiar to almost every one.

This is, that the influence of sensory impressions is greatly modified by our habitual state of mind in regard to them. Thus, if we are accustomed to *attend* to these impressions, and our perception of them is thus *increased* in acuteness, we are much more easily aroused by them than by others which are in themselves much stronger, but of which we have been accustomed to entertain an utter disregard. Thus, most sleepers are aroused by the sound of their own names uttered in a low tone, when it requires a much louder sound of a different description to produce any manifestation of consciousness. The same thing is seen in comatose states; a patient being often capable of being momentarily aroused by shouting his name into his ear, when no other sound produces the least effect. The following circumstance, communicated to the author by a naval officer of high rank, is a most apposite illustration of this principle. When a young man, he was serving as signal-lieutenant under Lord Hood, at the time when the French fleet was confined in Toulon harbour; and being desirous of obtaining the favourable notice of his commander, he devoted himself to his duty — that of watching for signals made by the look-out frigates — with the greatest energy and perseverance, often remaining on deck nineteen hours out of the twenty-four, with his attention constantly directed towards this one object. During the few hours which he spent in repose, his sleep was so profound, that no noise of an ordinary kind, however loud, would awake him; and it used to be a favourite amusement with his comrades, to try various experiments devised to test the soundness of his sleep. But if the word "signal" was even whispered in his ear, he was instantly aroused, and fit for immediate duty.

It is not requisite, however, that the sound should be one habitually attended to during the hours of watchfulness; for it is sufficient if it be one on which the attention has been fixed as that at which the slumberer is to arouse himself. Thus the medical man, even in his first profound sleep after a fatiguing day's work, is aroused by the first stroke of the clapper of his night-bell; and to those who are accustomed to rise every morning at the sound of an alarum-clock, the frequency and regularity of the occurrence do not diminish, but rather increase, the readiness with which it produces its effect, provided that the warning be promptly obeyed. On this usually depends the efficiency of the awakening sound; if it be disregarded as a thing to which there is no occasion to give heed, it very soon ceases to produce any effect, the entire peal not being sufficient to awake the sleeper; whilst, on the other hand, the first stroke is enough to break the repose of him who is impressed with the effectual desire of profiting by the warning. And thus it may happen that, of two persons in the same room, either shall be at once aroused by a sound which produces no disturbance in the slumbers of the other.— The influence of habitual attention is shown as much in the effect produced by the cessation, as in that of the occurrence, of sensory impressions. Thus in the case of the naval officer aroused by the suspension of the measured tread of the watch over his head, the knowledge possessed during the waking state that this suspension is either an act of negligence which requires notice, or indicates some unusual occurrence, doubtless augments the effect which the discontinuance of the sound would of itself produce.

Putting aside the awakening influence of external impressions, the period of natural termination of the slumber is greatly influenced by habit. Thus, many persons who are accustomed to rise at a particular hour, wake regularly at that hour, whether they have gone to rest early or late ; so that the act of spontaneously awakening is no proof that the desirable amount of repose has been obtained. But what is more remarkable is, that many individuals have the power of determining, at the time of going to rest, the hour at which they shall rise, so as to awake from a profound sleep at the precise time fixed upon. In others, however, the desire to rise at a particular hour only induces a state of restlessness throughout the night, destroying the soundness of the slumbers: the individual awakes many times in the night, with the belief that the hour is past, and very possibly oversleeps it after all, the system being worn out by the need of repose.

The *Amount of sleep* required by man is affected by many conditions, especially *age*, *temperament*, *habit*, and *previous exhaustion;* so that no general rule can be laid down upon the subject. The condition of the fœtus in utero may be regarded as one of continual slumber ; the energy of the organic functions being entirely directed to the building-up of the organism, whilst the apparatus of animal life is completely secluded from all the stimuli which could arouse it into activity. On its first entrance into the world, the infant continues to pass the greater part of its time in slumber; and this is particularly to be noticed in cases of premature birth,—the seven months' child seeming to awake only for the purpose of receiving food, and giving but little heed to any external objects when its internal cravings are satisfied; and even the eight months' infant being considerably less alive to sensory impressions, than one born at the full time. During the whole period of infancy and childhood, it is necessary for the development of the body that the *constructive* operations should be more energetic than the *destructive;* and, accordingly, we find that the period of sleep, during which the former take place without hindrance, is longer in proportion to the waking state, during which the latter are in play, than it is when full growth has been obtained.*

As age advances, the necessity for very rapid nutrition gradually diminishes, in consequence of the progressive approach to complete development ; and when the adult period has been attained, it is not requisite that the *constructive* processes should do more than balance the *destructive*. The amount of sleep requisite for this purpose, therefore, gradually diminishes, until it is reduced to (at most) one-third of the cycle of twenty-four hours. It is to be noticed that the sleep of children and young persons is not only longer than that of adults, but is also more profound. On the other hand, as age advances, and the bodily and mental activity of the waking state decreases, a smaller amount of sleep suffices ; or, if the slumber be protracted, it is usually less deep and refreshing. It may be noticed, however, that *very* old persons usually pass a large proportion of their time in sleep, or rather in dozing ; as if, in consequence of the want of energy of their nutritive operations, a very long period of repose is necessary to repair the waste which takes place during their short period of activity. It is stated† that " the celebrated De Moivre slept twenty hours out of the twenty-four ; and Thomas Parr latterly slept away by far the greater part of his existence." The repose of the aged is most apt to take place immediately after taking food ; while they solicit it in vain at that period at which, during the former years of their lives, they had been accustomed to enjoy it.

The amount of sleep, again, is much affected by *temperament*. It will generally be found that a plethoric habit of body, sustained by full diet, predisposes to sleep, provided the digestive powers be in a vigorous condition. Such persons frequently pass nine or ten hours in slumber, and maintain that they cannot be adequately refreshed by less. On the other hand, thin wiry people, in whom the " nervous" temperament predominates, usually take comparatively little sleep, notwithstanding the greater activity of their nervous system when they are awake ; but their slumber, while it lasts, is generally very deep. Persons of "lymphatic" temperament, heavy

* It is to be remembered, when we compare the condition of the nutritive operations during the period of growth, and after the complete development of the organism, that it is not in the mere amount of *accretion* that the difference consists. This would be the case if the new matter were merely *added* to the old, as in the formation of a new layer of wood in an exogenous stem. The growth of the animal fabric requires a continual new development of every part of it, involving a constant change in its materials ; and thus we see that the amount of food required by children, and the quantity of urea, and other products of the disintegration of the tissues set free in their excretions, bear a much larger proportion to those of the adult, than would be inferred from the relative bulk of the body at the two periods, and from its rate of increase during the former.

† Macnish, op. cit. p. 37.

passionless people, who may be said to live very slowly, are usually great sleepers; but this rather because, through the dullness of their perceptions, they are less easily kept awake by sensorial or mental excitement, than because they really require a prolonged cessation of activity. As they are half asleep during the waking state, so would it appear that the constructive operations must be far from active while they are asleep,—so little do they seem restored by the repose.

The amount of sleep, *cæteris paribus*, required by individuals, is very greatly influenced by *habit;* and, contrary to what we might anticipate, we find that the briefest sleepers have usually been men of the greatest mental activity. Thus Frederick the Great and John Hunter are said to have only required five hours' sleep out of the twenty-four. General Elliot, celebrated for his defence of Gibraltar, is recorded not to have slept more than four hours out of the twenty-four.* Sir Gilbert Blane states † that General Pichegru informed him that, " in the course of his active campaigns, he had for a whole year not more than one hour of sleep, on an average, in twenty-four hours." We suspect that if he had said " one hour of sleep at a time," he would have been nearer the truth. This we believe to have been the case with regard to the Duke of Wellington during the Peninsular campaigns. Dr. Elliotson says ‡, " I heard Baxter, the coachmaker, declare that he never took more than three hours' sleep during the most active period of his life." We doubt if it would be possible for any one to sustain a life of vigorous exertion with a smaller allowance than this.

The influence of habit is further shown in producing an aptitude for repose, or a readiness to wake, at particular periods. Thus, if a man is accustomed to go to rest at ten o'clock, and to rise at six, he will probably awake at six, even if he have not fallen asleep until twelve. And in like manner, if the morning sleep have been unusually protracted, the desire for sleep will probably return at the accustomed hour in the evening. The influence of habit is further exerted in producing an aptitude for sleep whenever the opportunity is afforded. Thus, the celebrated pedestrian Capt. Barclay, when accomplishing his extraordinary feat of walking 1000 miles in as many successive hours, obtained at last such a mastery over himself that he fell asleep the instant he lay down. And the sleep of soldiers, sailors, and others, who may be prevented from obtaining regular periods of repose, but are obliged to take their rest at short intervals, may be almost said to come at command; nothing more being necessary to induce it than the placing the body in an easy position, and the closure of the eyes. On the other hand, habit favors the protraction of sleep. This was the case with Quin, the celebrated actor, who could slumber for twenty-four hours successively; and with Dr. Reid, the metaphysician, who could take as much food, and afterwards as much sleep, as were sufficient for two days.

It is needless to dwell upon the obvious fact, that, other things being equal, the amount of sleep required by man is proportional to the amount of mental exertion put forth during the waking hours; since this is an obvious result of what has been laid down as the cause of the demand for sleep. It may be remarked, however, that we must not measure the *amount* of sleep by its *duration* alone; since its *intensity* is a matter of equal importance. The light slumber which is disturbed by the slightest sounds, cannot be as renovating as the profound sopor of those whom no ordinary noise will awake.

There are certain states of the nervous system in which there is an *entire absence of sleep;* and this may continue for many days, or even weeks or months. Insomnia is, for instance, one of the characteristics of acute mania, and may also exist in various forms of monomania. It is usually, also, one of the symptoms of incipient meningeal inflammation. And it may constitute a specific disease in itself. In all these cases, however, the preponderance of the *destructive* processes over the *constructive* manifests itself, sooner or later, in the exhaustion of the mental and bodily powers. Thus mania, when prolonged or frequently occurring, subsides into dementia. When meningitis (or rather inflammation of the surface of the hemispheric ganglia) is fully developed, a rapid disintegration of nervous matter takes place, as indicated by the large amount of alkaline phosphates in the urine.* The same would probably be detected in cases of idiopathic insomnia; which state, if it continue for any length of time, is sure to be followed by a great sense of wretchedness and prostration, frequently accompanied by continual restlessness. Such effects, too, in a less aggravated degree, result from habitual *deficiency* of sleep; whether this results from emotional excitement, which keeps repose at bay, or from a voluntary determination to keep the intellect in activity. This is a very common occurrence among industrious students, who, with a laudable desire for distinction, allow themselves less than the needed quantum of repose. Headache, tension, heat, throbbing, and various other unpleasant sensations in the head, give warning that the brain is being overtasked; and if this warning be not taken, sleep, which it was at first difficult to resist, becomes even more difficult to obtain; a state of general restlessness and feverish excitement are induced; and if, in spite of this, the effort be continued, serious consequences, in the form of cerebral inflammation, apoplexy, paralysis, fever, insanity, or loss of mental power, more or less complete, are nearly certain to be induced. Some individuals can sustain such an effort much longer than others, but it is a great mistake to suppose that they are not

* Macnish, op. cit. p. 34.
† Medical Logic, p. 83.
‡ Physiology, p. 601.

* See Dr. Bence Jones in Phil. Trans. 1846.

equally injured by it; in fact, being possessed with the belief that they are not suffering from the exertion, they frequently protract it until a sudden and complete prostration gives a fearful demonstration of the cumulative effects of the injurious course in which they have been persevering. Those, consequently, who are earlier forced to give way, are frequently capable of accomplishing more in the end.

In regard to the degree of *protraction* of sleep which is consistent with a healthy state of the system in other respects, it is difficult to speak with certainty. Of the numerous well-authenticated instances on record*, in which sleep has been continuously prolonged for many days or even weeks, it is enough here to state that they cannot be regarded as examples of natural sleep; the state of such persons being more closely allied to hysteric coma. An unusual tendency to proper sleep generally indicates a congested state of the brain, tending to apoplexy; and it has been stated that apoplexy has been actually induced by the experimental attempts to ascertain how large a proportion of the diurnal cycle might be spent in sleep. This effect may be readily explained, if we regard it as a general law of the capillary circulation, that its rate is increased by functional activity, and diminished by inactivity; for whilst congestion of the brain arising from other causes will tend to produce sleep, through the augmented pressure it occasions, mental inactivity, if encouraged and persisted in, will itself tend to produce congestion.

Thus, on either side, inattention to the dictates of Nature in respect to the amount of sleep required for the renovation of the system, becomes a source of disease, and should therefore be carefully avoided.

DREAMING.

We have hitherto spoken of sleep in its most complete or profound form,—that is, the state of complete unconsciousness. But with the absence of consciousness of external things, there may be a state of mental activity, of which we are more or less distinctly conscious at the time, and of which our subsequent remembrance in the waking state also varies in completeness: the impression being sometimes vivid, definite, and enduring; sometimes shadowy and evanescent; sometimes not amounting to more than the feeling that we have dreamed; and sometimes not even this being preserved, notwithstanding that there may be positive assurance that the sleep has been thus disturbed. This state, known as *dreaming*, is one of the highest interest to the psychologist; but the limits imposed upon us forbid our doing more than enumerate its leading phenomena.

The chief feature of the state of dreaming appears to be, that there is an entire *absence of voluntary control* over the current of thought; so that the principle of *suggestion*—one thought calling up another, according to the laws of association—has unlimited operation. Sometimes the train of thought thus carried on is remarkably consistent. We witness scenes that have occurred during our waking hours, and seem to hear, see, move, talk, and perform all the actions of life. We may experience every kind of mental emotion, and may even compare, reason, judge, and will, during our sleep; and our reasoning processes have frequently a remarkable clearness and completeness,—the data on which they are founded being supposed to be accurate. This consistency is usually the greatest, when the mind simply takes up a train of thought on which it had been engaged during the waking hours, not long previously; and it may even happen that, in consequence of the freedom from distraction occasioned by the suspension of ordinary sensations, the intellectual operations may be carried on during sleep with uncommon vigour and success. Thus, to name only two instances, Condorcet saw, in his dreams, the final steps of a difficult calculation, which had puzzled him during the day; and Condillac states that, when engaged with his "Cours d'Etude," he frequently developed and finished a subject in his dreams, which he had broken off before retiring to rest.

The imagination, equally with the reasoning processes, sometimes moves in a consistent course. Thus, Dr. Good relates the case of a friend who composed a little ode of about six stanzas, and set the same to agreeable music, in his sleep, the impression remaining so vividly that he was able to write down both the words and music on awaking in the morning; and Coleridge relates of himself that his fragment, entitled "Kubla Khan," was composed during sleep, which had come upon him whilst reading the passage in "Purchas's Pilgrimage" on which the poetical description is founded, and was written down immediately on awaking. The images, he says, "rose up before him as things, with a parallel production of the correspondent expressions, without any sensation or consciousness of effort." It would seem necessary, in most cases of this kind, that the results should be committed to paper immediately on waking, before the train of thought, continued from the dream, has been disturbed by any other. Thus, Coleridge tells us that, after having written for some little time, he was interrupted by a person on business, who continued with him above an hour; and on the departure of his visitor, he found, to his surprise and mortification, that "though he still retained some vague and dim recollection of the general purport of the vision, yet, with the exception of some eight or ten scattered lines and images, all the rest had passed away like the images on the surface of a stream into which a stone had been cast; but, alas! without the after-restoration of the latter." In other cases, a strong general impression of what has passed through the mind in sleep may remain on waking, without power of recalling the particulars. This was the case in the well-known instance of the musician Tartini, to whom the

* Such, for example, as that of Samuel Chilton (Phil. Trans., 1694), and that of Mary Lyall (Trans. of Roy. Soc. of Edinb., 1818).

arch-fiend appeared in his sleep, and was challenged by him to a trial of skill: the dreamer lay entranced by the transcendent performance of his visitor, which surpassed anything he had ever heard or conceived; on awaking, however, he could not reproduce the succession of notes, although he immediately seized his violin, and endeavoured to do so; but, under the strong general impression of what he had heard, he produced a new composition, which retains the name of the "Devil's Sonata."

But, although dreams *may* possess a remarkable coherence, whether as regards processses of reasoning, or the new combinations of the imagination, the general fact is, that such coherence is altogether wanting, and that there is a complete incongruousness in the thoughts and images which pass through our minds. All probabilities, and even possibilities of "time, place, and circumstance" are violated; the dead pass before us as if alive and well; even the sages of antiquity hold personal converse with us; our friends at the antipodes are brought upon the scene, or we ourselves are conveyed thither, without the least perception of distance; and the strangest combinations of reality and fancy are presented, either as objects passing before our consciousness, or as affecting our own condition. But of this incongruity we are seldom in the least aware. We are not capable of testing the probability or possibility of the phenomena by our ordinary experience. And, as a consequence of this, nothing surprises us in dreams; the feeling of surprise being the result, and indeed the measure, of our perception of the unlikelihood of a phenomenon. Not only is there usually a want of congruity in the intellectual processes, but a great disturbance in the ordinary play of the emotions. "Thus, in our dreams we may walk on the brink of a precipice, or see ourselves doomed to immediate destruction by the weapon of a foe or the fury of a tempestuous sea, and yet feel not the slightest emotion of fear; though, during the perfect activity of the brain, we may be naturally disposed to the strong manifestation of this feeling. Again, we may see the most extraordinary object or event without surprise, perform the most ruthless crime without compunction, and see what in our waking hours would cause us unmitigated grief, without the smallest feeling of sorrow." * This is, however, by no means uniformly the case. In fact, our emotions in the dreaming state are often highly wrought; and it frequently seems that the excitement of some particular emotion gives the direction to the whole train of thought, and causes it to possess an unusual coherence and probability. This is most remarkable, perhaps, when the emotion in question has greatly occupied the mind in the previous waking hours. Thus, a female, whose husband is at sea, and for whose safety she naturally feels anxious, especially in stormy weather, is very apt to dream of shipwreck and all its attendant circumstances; or, on the other hand, a man in love dreams of his mistress, of married life, and of its various enjoyments. Even here, however, the congruity is frequently interrupted by the intervention of some strange occurrence; the oddity of which may be perceived by the dreamer as being discordant, not with the intellectual but with the emotional state.

* Prof. Wheatstone, quoted in Elliotson's Physiology, p. 621.

In simple dreaming, as there is a loss of voluntary control over the current of thought, so is there an absence of control over the muscular system. Movements expressive of emotions, however, may still take place, and may afford to the by-stander an indication of what is passing in the mind of the dreamer. The indications of fear, horror, or disgust, or of hope, rapture, or desire, — laughter or weeping, smiles or frowns,— may all display themselves, when there is an absolute cessation of all voluntary movements. This is remarkably the case in attacks of *incubus*, or nightmare; in which the dreamer is oppressed by intolerable distress, from which he makes vain attempts to free himself. His distress may be expressed by moans, or by the agitation of his countenance; but none of his fancied efforts are indicated by any respondent movements. This condition may subside into a state of tranquil slumber, or the agitation may increase to such a pitch as to awake the sufferer; and as the first act of the waking state is usually to cry out or kick violently, it has been supposed that the return of volition has been the cause, instead of being the effect, of the cessation of the oppressive dream. There are cases, however, in which the dreamer executes movements in consonance with *ideas* passing through his mind, — such as would, in the waking state, be termed voluntary; but these must be considered as belonging rather to the category of somnambulism than to that of simple dreaming.

The direction of the current of thought in dreaming is often given by impressions on the organs of sense, which influence the mental operations, by calling up associated ideas, without being recognized and perceived as distinct sensations. Thus, Dr. James Gregory, having applied a hot bottle to his feet on going to bed, dreamt that he was walking up Etna and finding the ground intolerably hot. On another occasion, he dreamt of spending a winter at Hudson's Bay, and of suffering much distress from the intense frost; this evidently the consequence of his having thrown off the bed-clothes in his sleep, and of his having been reading, a few days before, a very particular account of the state of the colonies in that country during winter. Dr. Reid, having a badly-dressed blister on his head, dreamt that he was being scalped by Indians; and a man in a damp bed, that he was being dragged through a stream. A gouty man, when beginning to feel his pain in his sleep, may dream he is on the rack before inquisitors. The sound of music may excite delightful dreams. M. Girou de Buzareingues * made some curious experiments on

* Journal de Physiologie, tom. viii.

this point, and directed at pleasure the character of his dreams. In his first experiment, having allowed the back of his head to be uncovered during sleep, he thought he was at a religious ceremony in the open air; the custom of the country in which he lived being to keep the head covered excepting on some rare occurrences, among which was the performance of religious ceremonies. On waking he felt cold at the back of the neck, as he frequently had when present at the real ceremonies. He repeated the experiment in two days, with the same result. In a third experiment, he left his knees uncovered, and dreamt that he was travelling at night in the diligence; and all travellers know, he observes, that it is chiefly at the knees that they feel cold when travelling by that conveyance at night. The very remarkable degree in which this influence of external impressions is exerted, when sleep is being induced by the agency of certain narcotics, will be presently noticed. By the use of the term "external" is here meant that which is external to the mind itself. The dream may originate in impressions derived from any part of the bodily frame. Thus we find that indigestion is a very common cause of nightmare, and that an irritable state of the genital apparatus provokes lascivious dreams. When the external impressions are recognized as *sensations*, and the dreamer's current of thought completely follows their guidance, so that even the meaning of spoken language is appreciated, the condition approximates to that of Somnambulism.

One of the most remarkable of all the peculiarities of the state of dreaming, is the rapidity with which trains of thought pass through the mind; a dream in which a long series of events has seemed to occur, and a multitude of images has been successively raised up, being often certainly known to have occupied but a few minutes or even seconds. This is best seen in those cases in which the dream has obviously originated in some sensory impression, which has also had the effect of arousing the sleeper. A very interesting example of this, in which a similar dream was produced in two individuals, husband and wife, from the same cause, came within the knowledge of the late Dr. James Gregory. It happened when the public mind was much excited in regard to the alarm of French invasion, and the gentleman who was the subject of it was himself a zealous member of the Edinburgh volunteer corps. Whilst asleep, between two and three o'clock in the morning, he dreamt of hearing the signal gun: he was immediately at the Castle, witnessed the proceedings for displaying the signals to alarm the country, and saw and heard a great bustle over the town, from troops and artillery assembling, especially in Princes Street. At this time he was roused by his wife, who awoke in a fright, in consequence of a similar dream, connected with much noise and the landing of the enemy, and concluding with the death of a particular friend of her husband's, who had served with him as a volunteer. The origin of this remarkable occurrence was ascertained, in the morning, to be the noise produced in the room above by the fall of a pair of tongs. How long the dream had continued in this instance is uncertain; evidently not for a period in the least comparable to that required for the actual occurrence of the events that had passed through the mind of each; and it is probable, from many similar cases, that the lady was awoke by the noise rather than by the fright. Thus a gentleman dreamt that he had enlisted as a soldier, joined his regiment, deserted, was apprehended, carried back, tried, condemned to be shot, and at last led out for execution. After all the usual preparations, a gun was fired; he awoke with the report, and found that a noise in an adjoining room had both produced the dream and awoke him. The same feeling of duration, arising out of the number of images passing in succession through the mind, is often experienced when we are well assured that the whole duration of our sleep has not exceeded a few moments. We have known a clergyman fall asleep in his pulpit during the singing of the psalm before sermon, and awake with the conviction that he must have slept for at least an hour, and that the congregation must have been waiting for him; but on referring to his psalm-book, he has been consoled by finding that his slumber has lasted no longer than during the singing of a single line. There would not seem, in fact, to be any limit to the amount of thought which may thus pass through the mind of the dreamer, in an interval so brief as to be scarcely capable of measurement; and this view is confirmed by the circumstance, now well attested, that it is a common occurrence in drowning for the whole previous life of the individual to be presented instantaneously to his view; with its every important incident vividly impressed on his consciousness, just as if all were combined in a picture, every part of which could be taken in at a glance. This, again, is connected with the fact that the operation of the associative principle may reproduce in dreams the remembrance of facts long since forgotten in the waking state. Such, however, is by no means peculiar to the state of dreaming; for in the waking state we often retrace involuntarily and unexpectedly something which we have in vain attempted to recall at will, and which might be said to have passed from our mental grasp.

From the foregoing and other similar facts it has been argued, that *all* our dreams really take place in the act of falling asleep or of awaking; so that even when we fancy that we have been dreaming all night, our unconsciousness has been really complete, except at these momentary intervals. That this doctrine cannot be altogether true is obvious from the fact, that we can frequently detect the character of a dream, and even in some degree trace its progress, by the expression of the sleeper's countenance; so that dreams certainly *may* occupy time, and occur during ordinary sleep. On the other hand, it may be freely admitted that the apparent duration of our dreams does not afford the least measure of the time they have really occupied; and that it is probable that even when our sleep has seemed most disturbed by them, we have really passed a larger portion of the night in a state of complete unconsciousness than the mere impression left by our dreams would allow us to believe. But it has been questioned by some, on the other hand, whether there is ever such a state as that of complete unconsciousness. It is affirmed that the mind *can never* be entirely inactive; and that every body, in fact, does dream throughout the period of sleep, although the dreams may not be remembered in the waking state. This statement is rather based upon the hypothesis with which it commences, than upon any positive facts; and as it requires us to give up the simple teachings of ordinary experience, for the reception of a mere metaphysical dogma, the physiologist need not concern himself with the discussion.

On the whole, it may be said that dreaming indicates that sleep is imperfect; and this view harmonises with the fact that between dreaming and the waking state there are various connecting gradations. Thus, reverie or day-dreaming differs from the dreaming of the sleeper, not so much in the condition of the mind and its instrument the cerebrum, as in that of the sensorium, which is not so completely withdrawn in the former case, as it is in the latter, from the consciousness of external impressions. In sleep, on the other hand, the dreamer may have a consciousness of the unreality of the images that arise in his mind, and may even make a voluntary and successful effort to prolong them if agreeable, or to dissipate them if unpleasing; thus evincing the presence of that power of control over the current of thought, the want of which is one of the best characteristics of ordinary dreaming, as it is also of insanity, and indicating, therefore, an unusual approximation to the vigilant condition.

The action of narcotics on the nervous system presents many curious illustrations of the foregoing statements regarding the nature and phenomena of dreaming. There are some which have the power of inducing every condition intermediate between an unusual activity of the thoughts and a state of complete stupor, according to the dose taken. This is the case to a certain degree with opium; but still more decidedly with the extract of *Cannabis Indica*, a preparation of whch, known under the names of Hachisch and Dawamesc, is much used in the East for the production of a species of agreeable intoxication. The first effect of a dose of this substance is usually to produce a moderate exhilaration of the feelings and an unusual activity of the intellectual powers; but this activity gradually frees itself from voluntary control. The individual feels himself incapable of fixing his attention upon any subject; his thoughts being continually drawn off by a succession of ideas which force themselves (as it were) into his mind, without his being able in the least to trace their origin. These speedily occupy his attention, and present themselves in strange combinations, so as to produce the most fantastic and impossible creations. By a strong effort of the will, however, the original thread of the ideas may still be recovered, and the interlopers driven away. These lucid intervals successively become of shorter duration, and can be less frequently procured by a voluntary effort; for the internal tempest becomes more and more violent, the torrent of disconnected ideas increases in power so as completely to arrest the attention, and the mind is gradually withdrawn altogether from the contemplation of external realities, being engrossed by the consciousness of its own internal workings. There is always preserved, however, a much greater amount of self-consciousness than exists in ordinary dreaming; the condition rather corresponding with that just referred to, in which the sleeper *knows* that he is dreaming. The succession of ideas has at first less of incoherence than in ordinary dreaming, the ideal events not departing so far from possible realities; and the disorder of the mind is at first manifested in errors of sense, in false convictions, or in the predominance of one or more extravagant ideas. These ideas and convictions are generally not altogether of an imaginary character, but are called up by external impressions, which are erroneously interpreted by the perceptive faculties. The error of perception is remarkably shown in regard to time and space; minutes seem hours, hours are prolonged into years, and at last all idea of time seems obliterated, and past and present are confounded together as in ordinary dreaming: and in like manner, streets appear of an interminable length, and the people at the other end seem to be at a vast distance. Still there is a certain consciousness of the deceptive nature of these illusions, which, if the dose be moderate, is never entirely lost.

The effect of a full dose, however, is at last to produce the complete withdrawal of the mind from any distinct comprehension of external things; the power of the will over the current of thought is in like manner suspended, and the condition of the mind becomes the same in all essential particulars with that of the ordinary dreamer; differing in this chiefly, that the feelings are more strongly exerted, and that they still take their tone almost entirely from external impressions. Thus, says M. Moreau*, "It will be entirely dependent on the circumstances in which we are placed, the objects which strike the eyes, the words which fall on our ears, whether the most lively sentiments of gaiety or of sadness shall be produced, or passions of the most opposite nature shall be excited, sometimes with extraordinary violence; for irritation

* Du Hachisch et de l'Aliénation Mentale, Etudes Psychologiques, p. 67.

shall pass rapidly into rage, dislike to hatred, and the desire of vengeance and the calmest affection to the most transporting passion. Fear becomes terror, courage is developed into rashness which nothing checks, and which seems not to be conscious of danger, and the most unfounded doubt or suspicion becomes a certainty. The mind has a tendency to exaggerate everything, and the slightest impulse carries it along. Those who make use of the hachisch in the East, when they wish to give themselves up to the intoxication of the *fantasia*, take great care to withdraw themselves from everything which could give to their delirium a tendency to melancholy, or excite in them anything else than feelings of pleasurable enjoyment. They profit by all the means which the dissolute manners of the East place at their disposal. It is in the midst of the harem, surrounded by their women, under the charm of music and of lascivious dances executed by the Almees, that they enjoy the intoxicating dawamesc; and with the aid of superstition, they find themselves almost transported to the scene of the numberless marvels which the Prophet has collected in his Paradise."*

SOMNAMBULISM.

Our history of sleep would be incomplete without some account of a state which is closely allied to it, though differing from it in several important particulars. The phenomena of somnambulism are so varied, that it is very difficult to frame any definition capable of including them all; and we prefer characterising the state by saying that it may be considered as an *acted dream*,—differing from ordinary dreaming in the two following points. In the first place, the train of thought is more under the direction of sensations derived from without; and, secondly, the muscular system is so completely under the control of the mind, as not merely to give expression to its emotional states, but also to act in respondence to its volitions. As in dreaming, there would seem to be, in true somnambulism, a complete want of voluntary control over the current of thought, but there is not the same degree of mental activity; and in particular the operation of the associative principle is so much more restricted, that there is little or none of that incoherence or incongruity in the ideas brought up, which is so peculiar in ordinary dreaming. On the contrary, reasoning processes are often carried out with extraordinary clearness and correctness; the mind being intently fixed upon them to the exclusion of all other considerations. This *exclusiveness*, indeed, is one of the most remarkable characteristics of the condition. Whilst the attention of the mind remains fixed upon any object, either perceived by the senses or brought up by the act of conception, nothing else is felt. Thus there may be complete insensibility to bodily pain, the somnambulist's whole attention being given to that which is passing within the mind. Yet, in an instant, by directing the attention to the organs of sense, the anæsthesia may be succeeded by the most acute sensibility. So, again, when the attention is fixed upon a certain train of thought, whatever is spoken in harmony with it is heard and appreciated by the somnambulist; but whatever is in discordance with it is entirely disregarded. The character of the intellectual operations partakes of this peculiarity. As just now stated, the reasoning processes are usually accurately and definitely carried on, so that the conclusion will be sound, provided that the data have been correct. Thus, a mathematician will work out a difficult problem, or an orator will make a speech appropriate to a given subject. But the usual defect of the intellectual operations carried on in this condition is, that, owing to their very intensity, the attention is drawn off from the considerations which ought to modify them; and thus it happens that the result is often palpably inconsistent with the teachings of ordinary experience, and will be admitted to be so by the somnambulist when the former are brought to his mind.

The state of somnambulism may pass, on the one hand, into that of ordinary dreaming, so that it is difficult to draw the line between the two. Thus, the ordinary "talking in the sleep" may be referred to one or the other condition, according to the definition of each that we may adopt. In our own arrangement, they fall under the second head: because the vocal movements are expressions of the intellectual processes that are taking place in the mind; and because, in most cases of this kind, the sleep-talker hears and comprehends what is said to him, provided that this harmonises with what is going on within, and will answer rationally, so as to sustain a conversation. Thus, we knew a young lady at school, who frequently began to talk after having been asleep an hour or two; her ideas almost always ran upon the events of the previous day; and if encouraged by leading questions addressed to her, she would give a very distinct and coherent account of them; frequently disclosing her own peccadilloes and those of her school-fellows, and expressing great penitence for the former, whilst she seemed to hesitate about making known the latter. To all ordinary sounds, however, she seemed perfectly insensible. A loud noise would awake her, but

* The celebrated oriental scholar, M. Sylvestre de Sacy, appears to have made it pretty plain that our word *assassin* is derived from *Hachischin*, in the following manner. It is well known that the term was originally employed in Syria, to designate the followers of the "Old Man of the Mountain," who were accustomed to devote themselves with blind obedience to the execution of the orders of their chief, sacrificing themselves or others with equal readiness. Their education tended in every way to impress upon them this duty; and as a reward for its performance, they were promised after death all the sensual pleasures they could imagine,—a foretaste of these being every now and then given to them by intoxicating them with *hachisch*, in the midst of scenes in which everything was provided to gratify their senses. In this manner, a sort of fanaticism was gradually induced, which rendered them fit agents of the murderous designs of their master.

was never perceived in the sleep-talking state; and if the interlocutor addressed to her any questions or observations that did not fall in with her train of thought, they were completely disregarded. By a little adroitness, however, she might be led to talk upon almost any subject; a transition being gradually made from one to another by means of leading questions.

The well-known case of the officer, narrated by Dr. James Gregory, is one of the same intermediate class; rather allied, in our apprehension, to somnambulism than to ordinary dreaming. This gentleman, who served in the expedition to Louisburgh in 1758, was in the habit of *acting* his dreams; and their course could be completely directed by whispering into his ear, especially if this was done by a friend with whose voice he was familiar; so that his companions in the transport were in the constant habit of amusing themselves at his expense. At one time they conducted him through the whole progress of a quarrel, which ended in a duel; and when the parties were supposed to be met, a pistol was put into his hand, which he fired, and was awakened by the report. On another occasion they found him asleep on the top of a locker or bunker in the cabin, when they made him believe he had fallen overboard, and exhorted him to save himself by swimming. He immediately imitated all the motions of swimming. They then told him that a shark was pursuing him, and entreated him to dive for his life. He instantly did so, with such force as to throw himself entirely from the locker upon the cabin-floor, by which he was much bruised, and awakened of course. After the landing of the army at Louisburgh, his friends found him one day asleep in his tent, and evidently much annoyed by the cannonading. They then made him believe that he was engaged, when he expressed great fear, and showed an evident disposition to run away. Against this they remonstrated; but, at the same time, increased his fears, by imitating the groans of the wounded and the dying; and when he asked, as he often did, who was down, they named his particular friends. At last they told him that the man next himself in the line had fallen, when he instantly sprung from his bed, rushed out of the tent, and was roused from his danger and his dream together, by falling over the tent-ropes. After these experiments, he had no distinct recollection of his dreams, but only a confused feeling of oppression and fatigue; and used to tell his friends that he was sure they had been playing some trick upon him. This is another point of conformity with somnambulism; one of whose most distinctive peculiarities it is, that neither the trains of thought nor any of the events of the somnambulistic state are remembered in the ordinary waking condition, though the impression of the feelings strongly excited during that state, is sometimes continued. Both the trains of thought and the events of the somnambulistic state, however, are frequently remembered with the utmost vividness on the recurrence of that state, even at a very distant interval: and of the interval, however long it may have been, there is no consciousness whatever. The same thing, but more rarely, occurs in dreaming; the dreamer sometimes recollecting a previous dream, and even taking up and continuing its thread, although he could not in the least retrace it in his waking state.

A remarkable case of spontaneous somnambulism, which occurred within our own experience, will serve to illustrate many of the most characteristic features of the condition in question. The subject of it was a young lady of highly nervous temperament; and the affection occurred in the course of a long and trying illness, in which almost every form of hysteria, simulating tetanus, epilepsy, coma, and paralysis, had successively presented itself. Although natural somnambulism ordinarily arises out of ordinary sleep, yet in this instance the patient usually passed into the somnambulistic condition from the waking state; the transition being immediately manifested by the peculiar expression of the countenance. In this condition her ideas were at first entirely fixed upon one subject—the death of her only brother, which had occurred some years previously. To this brother she had been very strongly attached; she had nursed him in his last illness; and it was perhaps the return of the anniversary of his death about the time when the somnambulism first occurred, that gave to her thoughts that particular direction. She talked constantly of him, retraced all the circumstances of his illness, and was unconscious of anything that was said to her which had not direct reference to this subject. On one occasion she mistook her sister's husband for her lost brother; imagined that he was come from heaven to visit her; and kept up a long conversation with him under this impression. This conversation was perfectly rational on her side, allowance being made for the fundamental errors of her data. Thus, she begged her supposed brother to pray with her; and on his repeating the Lord's Prayer, she interrupted him after the sentence "forgive us our trespasses," with the remark, "But *you* need not pray thus; *your* sins are already forgiven." Although her eyes were open, she recognised no one in this state, not even her own sister, who, it should be mentioned, had not been at home at the time of her brother's illness.

On another occasion, it happened that, when she passed into this condition, her sister, who was present, was wearing a locket, containing some of their deceased brother's hair. As soon as she perceived this locket, she made a violent snatch at it, and would not be satisfied until she had got it into her own possession, when she began to talk to it in the most endearing and even extravagant terms. Her recognition of this locket, when she did not perceive that her sister was the wearer of it, was a very curious fact, which may be explained in two ways, each of them in accordance with the known laws of somnambulism. Either the concentration of her thoughts on this one subject caused her to remember only that which was *immediately* connected with her brother; and her unconsciousness of the presence of her sister might be due to the absence of the latter at the time of his death, which caused her to be less connected with him in the thoughts of the somnambulist:—or it may have happened that she was directed to this locket by the sense of smell, which is frequently exalted in a very remarkable degree in the somnambulistic state. (See SMELL.) Her feelings were so strongly excited by the possession of the locket, that it was judged prudent to check their continuance; and as she was inaccessible to all entreaties on the subject, force was employed to obtain it from her. She was so determined, however, not to relinquish it, and was so angry at the gentle violence used, that it was found necessary to abandon the attempt; and she became calmer after a time, and at last passed off into ordinary sleep, which was in her case the successor, instead of being (as it usually is) the predecessor, of the somnambulistic state. Before going to sleep, however, she placed the locket under her pillow, remarking, "Now I have hid it safely, and they shall not take it from me." On awaking in the morning, she had not the slightest consciousness of what had passed; but the impression of the excited feelings remained; for she remarked to her sister,—"I cannot tell what it is that makes me feel so; but every time that S—— comes near me, I have a kind of shuddering sensation;"—the individual named being a servant, whose constant attention to her had given rise to a feeling of strong attachment on the side of the invalid, but who had been the chief actor in the scene of the previous evening. This feeling wore off in the course of a day or two. A few days afterwards, the somnambulism again recurred; and being upon her bed at the time, she immediately began to search for the locket under her pillow. In consequence of its having been removed in the interval (in order that she might not, by accidentally finding it, be led to inquire into the cause of its presence there, of which it was thought better to keep her in ignorance), she was unable to find it; at which she expressed great disappointment, and continued feeling for it, with the remark, "It *must* be there; I put it there myself a few minutes ago; and no one can have taken it away." In this state, the presence of S—— renewed her previous feelings of anger; and it was only by sending S—— out of the room that she could be calmed and induced to sleep.

This patient was the subject of many subsequent attacks, in every one of which the anger against S—— revived; until the current of thought changed, no longer running exclusively upon what related to her brother, but becoming capable of direction by *suggestions* of various kinds presented to her mind, either in conversation, or, more directly, through the several organs of sense. On one occasion, the attack having come on whilst she was alone, she managed to make her way down stairs, along a passage, and out into the garden by a back-door, although completely paraplegic,—a very curious instance of *sleep-walking*. So nearly did her condition, in some of these attacks, approach the waking state, that the case might then be almost regarded as one of *double consciousness*,—that very curious affection, of which the subject seems to lead two distinct lives, A and B, in neither remembering what takes place in the other, but each state being, as it were, continuous with itself.

The preceding case is well adapted to illustrate the general characters of the somnambulistic condition: we have now to notice some of those peculiar phenomena which are presented in individual cases. The first of these to which we shall advert, is the extraordinary exaltation of the sensibility to external impressions through one or more of the organs of sense; which would seem to result, in some instances, from the concentration of the attention upon that one class of impressions, but which, in other cases, is independent of any such state of attention.* We have ourselves been particularly struck with this, in the somnambulism induced by the "hypnotic" process of Mr. Braid, to which we shall presently refer. We have seen unequivocal proof that the sense of smell has been exalted to an acuteness at least equalling that of the most keen-nosed ruminant or carnivorous animal; that the sense of hearing has been rendered equally acute; and that the sense of touch has been exalted, especially in regard to temperature, to a degree that would be scarcely credible, were not the phenomena in perfect keeping with the exaltation of the other senses. We are not aware that the sense of sight has ever been thus acted on. In most somnambulists it is altogether suspended; and those who claim to possess the power of clairvoyance, reading words inclosed in opaque boxes, &c., do not refer their power of doing so to any unusual acuteness of their visual organs, but attribute it to the development of an entirely new faculty, for the operation of which any such optical instrument as the eye is altogether unnecessary. Among the senses most commonly exalted in somnambulism, is that "muscular sense" by which all our voluntary movements are guided; and this seems to be so much increased in acuteness, as quite to replace the visual sense, in the performance of many of those operations for which sight is ordinarily requisite. Thus we find that sleep-walkers make their way over the roofs of houses,

* The young lady whose case we have just detailed, exhibited, in a former attack of nervous disorder, a most extraordinary acuteness of the auditory sense, so that it was difficult to prevent her from hearing everything that passed in the house. Of a conversation held in an ordinary tone, in a room two stories below, she could hear every word as distinctly as if it had passed in her own chamber. Yet she did not suffer pain, as might have been expected, from the excessive loudness of ordinary sounds.

steadily traverse narrow planks, and even clamber precipices; and this with far less hesitation than they would do in the waking state. The fact seems to be, that they are utterly unconscious of the danger they are incurring; and that the whole attention being fixed without any distraction upon the indications of the muscular sense, the requisite movements are performed under its guidance with steadiness and certainty. So, again, it is well known that somnambulists will write with their usual degree of neatness and regularity, when prompted to do so either by their own train of thought, or by some suggestion from without; and this, when it is perfectly certain that they cannot see. We have ourselves witnessed this in hypnotic experiments on two individuals, and made quite sure that vision could not be affording any assistance, by holding a large book between the eyes and hand of the writer. Not only were the lines well written, and at the proper distances, but the *i*'s were dotted and the *t*'s crossed; and in one instance, the writer went back half a line to make a correction, crossing off a word, and writing another above it, with as much correctness as if he had been guided by vision. The guidance of the muscular sense in this case may be compared to that which we ourselves receive from it, when ascending or descending a pair of stairs, or traversing a passage, to which we have previously been accustomed, in the dark; we know when we have come to the end, without having counted our steps, or in any way observed our progress, simply by the information we receive through the muscular sense. To the suspension, complete or partial, of the activity of one or more of the organs of sense, which may occur spontaneously, or may be induced by calling off the attention from it, reference has already been made.

The next point to be noticed is the readiness with which the train of thought may be guided, during the state of somnambulism, by the principle of *suggestion.* This is more, perhaps, the case in *artificial* or *induced* than in *natural* somnambulism; for in the latter there is frequently, as already pointed out, some dominant idea or set of ideas, from which the attention of the somnambulist cannot easily be distracted. In the former, the mind is like a weathercock, without the least fixity or self-control, but liable to be turned in any direction by the impressions to which it is subjected. It is one of the most curious and important of Mr. Braid's discoveries, that the suggestions conveyed through the muscular sense are among the most potent of any in determining the current of thought. Let the face, body, or limbs be brought into the attitude expressive of any particular feeling, or into a condition at all corresponding with that in which they would be placed for the performance of any voluntary action, and the corresponding mental state is at once called up. Thus, if the hand be placed upon the vertex, the somnambulist will frequently, of his own accord, draw his body up to its fullest height, and throw his head slightly back; his countenance then assumes an expression of the most lofty pride, and his whole mind is obviously possessed by the feeling. Where the first action does not of itself call forth the rest, it is sufficient to straighten the legs and spine, and to throw the head somewhat back, to arouse the feeling and the corresponding expression to its full intensity. During the most complete domination of this emotion, let the head be bent forward, and the body and limbs gently flexed; and the most profound humility then takes its place. So, again, if the angles of the mouth be gently separated from one another, as in laughter, a hilarious disposition is immediately generated; and this may be immediately made to give place to moroseness, by drawing the eyebrows towards each other and downwards upon the nose, as in frowning. Not only have we witnessed all these effects repeatedly produced upon numerous "hypnotised" subjects, but we have been assured by a most intelligent friend who has paid special attention to the psychological part of this enquiry, that having subjected himself to Mr. Braid's manipulations, and been only partially thrown into the "hypnotic" state, he distinctly remembers everything that was done, and can retrace the uncontrollable effect upon his state of mind which was produced by this management of his muscular apparatus.

So, again, not merely emotional states but definite ideas are thus excitable. Thus, if the hand be raised above the head, and the fingers are flexed upon the palm, the idea of climbing, swinging, or pulling at a rope is called up; if, on the other hand, the fingers are flexed when the arm is hanging down at the side, the idea excited is that of lifting a weight; and if the same be done when the arm is advanced forwards in the position of striking a blow, the idea of fighting is at once aroused, and the somnambulist is very apt to put it into immediate execution. On one occasion on which we witnessed this result, a violent blow was struck, which chanced to alight upon a second somnambulist within reach; his combativeness being thereby excited, the two closed, and began to belabour one another with such energy, that they were with difficulty separated. Although their passions were at the moment so strongly excited, that even when separated they continued to utter furious denunciations against each other, yet a little discreet manipulation of their muscles soon calmed them, and put them into perfect good humour. The power of the operator, in regulating the state of mind of such somnambulists, is almost unlimited; and surpasses the credibility of those who do not discern the very simple principle on which it is exercised. The facility with which particular feelings or ideas may thus be excited, will of course be dependent in part on the previous character and habits of the somnambulist.

Again, a very uncommon degree of power

may be determined to particular muscles, as Mr. Braid has shown, either by a suggestion (so to speak) applied directly to themselves, or by the induction of such a mental state as shall be most fitted to call them into energetic operation. Thus the extensor muscles of a limb may be excited to contraction by gently rubbing or pressing the surface above them; and this contraction may not merely raise the limb, but may keep it fixed in a cataleptiform manner for a much longer time than any voluntary effort could accomplish. This contraction may be caused to give way at any moment, by gently wafting a current of air over the same surface, which seems to call off the attention from the muscles to the skin. In order to throw an extraordinary degree of power into a group of muscles by a mental process, all that is required is to suggest the action, and to assure the somnambulist that it can be accomplished with the greatest facility if he will only determine to do it. Thus, we have seen one of Mr. Braid's hypnotised subjects, a man remarkable for the poverty of his muscular development, lift a twenty-eight pound weight upon his little finger alone, and even swing it round his head, — upon being assured that it was as light as a feather. We have every reason to believe that the personal character of this individual placed him above the suspicion of deceit; and it is obvious that if he had *practised* such a feat (which very few, even of the strongest men, could accomplish without practice), the effect would have been visible in his muscular development. The same individual declared himself altogether unable to raise a handkerchief from the table, after many apparently strenuous efforts; having been assured that its weight was too great for him to move. Of course, there was not an equal proof of the absence of deception in this second case as in the first; but if the reality of the first be admitted, there need be no difficulty in the reception of the second, since both are manifestations of that mental condition which has been shown to be so characteristic of this state, — the possession of the mind by a dominant idea, which, when infused into it (as it were) by the principle of suggestion, directs the bodily movements, and is not corrected by the teachings of ordinary experience, or even by present sensations, if the mental assurance be strong enough to cause these to be disregarded.

Of the *causes* of somnambulism, no very definite account can be given. In some persons this state recurs frequently, or even habitually; in others occasionally. In the case formerly detailed, its access might generally be traced to some strong mental emotion. Those in whom it presents itself *spontaneously* are said to be *natural* somnambulists; but it may be *induced*, not merely in them, but in others who have manifested no predisposition to it, by certain *artificial* procedures. In many cases this may be effected through the mind alone, the simple *expectation* of the result being sufficient to bring it about. Thus the Abbé Faria was accustomed to induce somnambulism by placing his patient in an arm-chair, and then, after telling him to shut his eyes and collect himself, pronouncing in a strong voice and imperative tone the word "dormez," which generally produced on the individual an impression sufficiently strong to give a slight shock, and occasion warmth, transpiration, and sometimes somnambulism. — The following case is another illustration of the effect of this state of expectation, acting in concurrence with a fixed position. The subject of it was a lady who had previously shown great susceptibility to the "mesmeric" and "hypnotic" processes. "We now requested our patient to rest quietly at the fire-place, to think of just what she liked, and look where she pleased, except at ourselves, who retreated behind her chair, saying that a new mode was about to be tried, and that her turning round would disturb the process. We very composedly took up a volume which lay on the table, and amused ourselves with it for about five minutes; when, on raising our eyes, we could see, by the excited features of other members of a little party that were assembled, that the young lady was once more *magnetised*. We were informed by those who had attentively watched her during the progress of our little stratagem, that all had been, in every respect, just as before. The lady herself, before she was undeceived, expressed a distinct consciousness of having felt our unseen passes streaming down the neck."*

Perhaps the most effectual of all modes of inducing somnambulism is that discovered by Mr. Braid, and practised extensively by him under the designation of hypnotism.† The following is his description of his mode of inducing it, and of the phenomena attending its production. "Take any bright object (I generally use my lancet-case) between the thumb and fore and middle fingers of the left hand; hold it from about eight to fifteen inches from the eyes, at such position above the forehead as may be necessary to produce the greatest possible strain upon the eyes and eyelids, and enable the patient to maintain a steady fixed stare at the object. The patient must be made to understand that he is to keep the eyes steadily fixed on the object, and the mind riveted on the idea of that one object. It will be observed that, owing to the consensual adjustment of the eyes, the pupils will be at first contracted; they will shortly begin to dilate, and after they have done so to a considerable extent, and have assumed a wavy motion, if the fore and middle fingers of the right hand, extended and a little separated, are carried from the object towards the eyes, most probably the eyelids will close involuntarily, with a vibratory motion. . . . After ten or fifteen seconds have elapsed, by gently elevating the arms and legs, it will be found

* Brit. and For. Med. Rev., vol. xix. p. 477.

† Neurypnology, or the Rationale of Nervous Sleep, considered in relation with Animal Magnetism, &c., by James Braid, M. R. C. S. E., &c.

that the patient has a disposition to retain them in the situation in which they have been placed, if he is intensely affected. If this is not the case, in a soft tone of voice desire him to retain the limbs in the extended position, and thus the pulse will speedily become greatly accelerated, and the limbs, in process of time, will become quite rigid and involuntarily fixed. It will also be found that all the organs of special sense, excepting sight, including heat and cold, and muscular motion or resistance, and certain mental faculties, are at first prodigiously exalted ; such as happens with regard to the primary effects of opium, wine, and spirits. After a certain point, however, this exaltation of function is followed by a state of depression, far greater than the torpor of *natural* sleep. From the state of the most profound torpor of the organs of special sense, and tonic rigidity of the muscles, they may at this stage be *instantly* restored to the *opposite* condition of extreme mobility and exalted sensibility, by directing a current of air against the organ or organs we wish to excite to action, or the muscles we wish to render limber, and which had been in the cataleptiform state. By mere repose the senses will speedily merge into the original condition again." We have ourselves frequently witnessed the induction of somnambulism after this method ; and whilst fully admitting its potency, we are bound to say that the almost invariable success which it has in the hands of Mr. Braid himself, appears partly due to the mental condition of the patient, who is usually predisposed to the " hypnotic " state by the expectation of its certain production, and by the assurance of a man of determined will that it *cannot* be resisted. When the hypnotic state, however, has been induced a few times in the manner just described, the subject can usually send himself to sleep very readily by looking at his own finger, brought sufficiently near the eyes to occasion a sensible convergence of their axes ; or even by simply standing still, and fixing the eyes on a distant point. In all cases, the fixation of the eyes is the circumstance of most importance; although the withdrawal of other stimuli has a decided influence in favouring the production of the effect. The peculiar condition of the *muscular* sense, as felt through the ophthalmic branch of the fifth pair, seems to have a closer relation with the subsequent state than has the condition of the visual sense; for the same effect may be produced at night, or in blind persons, if the eyes can be kept in a fixed position, especially in one that produces a feeling of muscular tension. And it seems to be in facilitating this, that the sense of sight comes into play in the operation just described. How far the mode in which the somnambulism is produced has an influence upon its phenomena, it may not be very easy to determine. For an account of these peculiarities, we must refer to Mr. Braid's treatise already quoted ; but we may cite the following, as having ourselves repeatedly witnessed it and satisfied ourselves of its reality. " The remarkable fact that the whole senses may have been in a state of profound torpor, and the body in a state of rigidity, and yet by very gentle pressure over the eye-balls the patient shall be instantly roused to the waking condition, as regards all the senses and mobility of the head and neck, in short, to all parts supplied with nerves originating above the origin of the fifth pair, and those inosculating with them,—whilst they will not be affected by simple mechanical appliance to other organs of sense,—is a striking proof that there exists some remarkable connection between the state of the eyes, and condition of the brain and spinal cord, during the hypnotic state. Another remarkable proof to the same effect is this ; Supposing the same state of torpor of all the senses, and rigidity of the body and limbs, to exist, a puff of air or a gentle pressure against *one* eye will restore sight to *that* eye, and sense and mobility to *one half of the body*—the same side as the eye operated on ;—but will leave the other eye insensible, and the other half of the body rigid and torpid as before." *

We consider that the experimental researches of Mr. Braid throw more light than has been derived from any other source upon the phenomena of *Mesmerism*. That there is much of reality mixed up with much imposture in these phenomena, is a conclusion at which most candid persons have arrived who have given their attention to them ; and we have little doubt that a searching investigation, carried on under the guidance of his results, would lead to something like a correct discrimination between the two. The induction of mesmeric somnambulism appears to us to be fully explicable by the facts we have previously stated, as to the influence of the mental condition of the patient,—namely, the state of expectation, and the additional confidence derived from the mental impression produced by the operator,—and as to the effect of the fixation of vision. The ordinary phenomena of the mesmeric somnambulism itself are in most respects identical with those of hypnotism, except in this particular,—that there seems to be a peculiar relation between the somnambulist and the mesmeriser, which does not exist between the somnambulist and any other individual, excepting one who is *en rapport* with the mesmeriser. This relationship may perhaps be not unreasonably regarded as the result of a dominant idea, which possessed the mind at the moment of falling asleep, and which continued to influence it so long as the somnambulism lasts. We have examined into the history of many cases, in which it was affirmed that mesmeric sleep was induced without any consciousness on the part of the subject of it that any influence was being exercised; but we have never been able to satisfy ourselves that such was unequivocally the case. When the patient was *expecting* the performance,

* Op. cit. p. 64. *note.*

and was waiting in quiescence for its commencement, the expectation alone was sufficient to induce the sleep. When the patient had *no* such expectation, all attempts to produce the sleep, that have come to our knowledge, have completely failed. Hence we are strongly inclined to the belief that the relation between the mesmeriser and the somnambulist is one of a purely mental character, and not the result of any new physical power. With regard to what have been termed the "higher phenomena" of mesmerism, we believe that without regarding them as the result of intentional deception, most of them are capable of receiving a very simple explanation on the principles already laid down, — namely, that in the state of somnambulism the senses, or some of them, are often endowed with a wonderful acuteness, which causes the mind to be acted on by impressions that might be affirmed to be too faint to be perceived; and that these impressions will suggest trains of thought, and give rise to respondent actions, which are frequently of a kind that the will *could* not produce. As to the reality of the so-called *clairvoyance*, repeated personal examination has led us to a negative conclusion. The sources of fallacy arising from the causes we have mentioned, as also from the tendency on the part of the bystanders to afford assistance by asking "suggestive" or "leading questions," and from their disposition to interpret the least shadow of a resemblance into a complete coincidence, are such as greatly to diminish the wonder that a firm belief in the reality of these phenomena should be entertained by many persons of excellent judgment and great discrimination and acuteness as to all ordinary matters.

A state in most respects corresponding with natural somnambulism is frequently induced by the inhalation of ether, chloroform, and other anæsthetic agents. Instead of being completely comatose, the patient, though quite unconscious of pain, may be awake to external impressions received through some of his organs of sense, so as during an operation to obey the directions given him in order to facilitate its performance; and yet he shall be completely unaware of what has taken place when the effects of the anæsthetic agent have gone off. But even the sense of pain may not be extinguished, and the patient may scream and struggle even more violently than in the waking state; and yet the whole is subsequently forgotten, or is remembered only as a troubled dream. It was further to be noticed that, during the employment of ether, the state of the nervous system induced by it appeared to be much influenced by the previous degree of confidence entertained by the patient as to its results. The more potent action of the chloroform, however, has prevented this influence from being so apparent.

(*W. B. Carpenter.*)

SMELL. — The sense through which we take cognizance of odours.

Of the nature of odorous emanations nothing is certainly known. They are generally supposed to consist of material particles of extreme minuteness, detached from the odorous body, and dissolved or suspended in the air. This idea derives its chief support from the facts that most odorous substances are volatile, that is, their loss of weight, when exposed to the air, shows that their particles really diffuse themselves through it, — that most strongly odorous substances are extremely volatile—and that circumstances which increase the volatility of such substances also augment their odorous powers. These general statements, however, are not without their exceptions. Thus, in the first place, we do not find that many gaseous substances are truly *odorous;* the pungent, irritating qualities, by which many of them are distinguished, not being perceived through the sense of smell but through that of touch. Again, although it is true that a great number of volatile liquids are odorous, the strength of their scent bears no constant proportion to their respective volatility; and water, which is so constantly diffused through the air, has no odorous property. And with regard to solids, we find that although some of those which are most strongly odorous are also volatile (such as camphor), yet this is not by any means universally the case; for it has been proved by experiment that no diminution in weight can be ascertained to take place in musk or amber, although they have been freely exposed to the atmosphere for many years, and have imparted their perfume to an almost incalculable volume of air. These considerations have led some philosophers to suppose that odorous emanations are not *material*, but *dynamical:* — in other words, that the impressions made upon our olfactory organ do not result from the contact of diffused particles detached from the odorous body; but that they are effected by a change propagated through the atmosphere or other medium, in the same manner as sound is produced by undulations that originate in the sonorous body, and are transmitted onwards, through some material medium, to the organ of hearing. There are strong objections, however, to this hypothesis. In the first place, we find that odours are not perceived unless the air, gas, or liquid in contact with the olfactory surface is, or has been, in direct continuity with the odorous body; the interposition of any substance which prevents the actual passage of the odoriferous medium being sufficient to prevent the transmission of the odour. This is by no means the case in regard to sound, or to any other agent that is known to be dynamically propagated; for we find many substances which are capable of *conducting* these agents, that is, of transmitting their influence through unlimited spaces; and this may be accomplished in spite of any number of interruptions in their continuity, provided the chain of conducting substances be complete. Thus, sonorous vibrations may be transmitted from air to liquids, from liquids to solids, from air to solids, from solids to air, &c.; and many such changes usually take place, before the vibrations originating in a sonorous body are communicated to the sentient extremities of the auditory nerve. The same is the case with heat, light, electricity, and other agents whose transmission is believed to be dynamical: that it is *not* the case in regard to odorous emanations must be regarded, therefore, as a powerful argument against the idea of their dynamical nature. Another argument may be derived from the well-known fact, that odorous emanations require such a *time* for their propagation, as corresponds rather with the *diffusion* of the odoriferous medium itself, than with the mere *conduction* of vibrations. Thus, in a house in which free communication is established throughout by passages, staircases, &c., but in which the course of air is not very direct from one part to another, any strong odour set free in one spot will be *gradually* diffused through the whole house, the rapidity being governed by the circumstances which favour or obstruct the movement of air. On the other hand, the transmission of sonorous undulations, which merely throw the air into vibration, is not dependent upon its movement, and is, indeed, but little influenced by it. This argument is, perhaps, yet more cogent than the former, and may be regarded as conclusive against the dynamical theory of odours.

It is not difficult to explain many of the apparent inconsistencies which attend the material theory. The varieties of the olfactive power among human beings are quite sufficient to prove, that a substance which is strongly odorous to one individual may not produce any impression on the smell of another, whose scent for other substances may nevertheless be very acute. And there is strong reason to believe that there is a great diversity in this respect amongst different species of animals, some appearing entirely insensible to odours which strongly affect others. That *we* do not appreciate an odour, therefore, is no proof of its non-existence; and we have no right to say of any volatile or gaseous substances, that they are not odorous, but simply that they are not odorous *to us*. Again, the sense of smell, like the other senses, is rather *relative* than *positive*; that is to say, it rather estimates a *change* in the condition of the surrounding medium, than its actual permanent state. This is fully proved by the fact that persons who habitually dwell amongst odours of any one kind, become, in time, entirely insensible to them, although their olfactive sense may remain of its full acuteness in regard to any different scent. This being the case, we at once perceive that water, oxygen, nitrogen, and carbonic acid *could* not, in accordance with the general laws of sensation, possess any odour to animals whose organs of smell are constantly imbued with them. We shall presently find that the moisture of the olfactory membrane is a necessary condition of its functional power; and thus neither fishes, which have their olfactory surface constantly bathed in water, nor air-breathing animals, whose pituitary membrane is lubricated with it, could take cognisance of any odorous properties which it might really possess. In like manner, the nasal cavities of animals being continually filled with a mixture of oxygen, hydrogen, and carbonic acid, these gases cannot excite the olfactive sense; whilst on the other hand, we can easily imagine that if animals were adapted to breathe hydrogen or its strongly odorous compounds, they would be insensible to the latter, whilst they might distinguish oxygen, nitrogen, or carbonic acid by their respective odours, just as readily as *we* distinguish phosphuretted, sulphuretted, or carburetted hydrogen.

Although it is through the atmosphere that odorous emanations are most readily conveyed, yet there can be no reasonable doubt that they may be transmitted through water also. Thus we find fishes provided with a complex organ of smell, which seems to be of considerable importance in directing them towards their prey. This may be inferred, not merely from the fact that the olfactive ganglia and nerves are of large size relatively to the rest of the encephalon, but also from the circumstance, well known to fishermen, that many fish are particularly attracted by odorous bait. Some anglers are even in the habit of scenting their bait with essential oils, in order to render it more alluring.

The general structure of the *organ of smell* in man has already been described (NOSE); but some particulars recently ascertained by Messrs. Todd and Bowman respecting the minute anatomy of the pituitary membrane, and the structure and distribution of the olfactory nerve, are too important to be passed by. That the true sense of smell is specially, if not exclusively, the endowment of the upper portion of the organ, has been inferred by anatomists from the limited distribution of the olfactory nerve, and by physiologists from the fact that odours are only perceived strongly when the odoriferous air is drawn into the upper part of the cavity. The lower part of the nasal cavity is properly to be regarded as the orifice of the respiratory passages: it is extremely sensitive to *irritants*, but it does not participate in the discrimination of *odours* properly so called; and its mucous membrane is covered with a ciliated columnar epithelium. On the other hand, the limits of the olfactive region "are distinctly marked by a more or less rich sienna-brown tint of the epithelium, and by a remarkable increase in the thickness of this structure compared with the ciliated region below; so much so, that it forms an opaque soft pulp upon the surface of the membrane, very different from the delicate, very transparent film of the sinuses and lower spongy bones. The epithelium, indeed, here quite alters its character, being no longer ciliated, but composed of an aggregation of superposed nucleated particles, of pretty uniform appearance throughout; except that, in many instances, a layer of those lying deepest, or almost deepest, is of a darker colour than the rest, from the brown pigment contained in the cells. These epithelial particles, then, are not ciliated; and they form a thick, soft, and pulpy stratum, resting on the basement membrane. The deepest layer often adheres after the others are washed away." The vessels of the olfactive membrane in the fœtus present a regular series of papillary loops; but these cannot be seen in the adult. "The olfactory filaments form a considerable part of the entire thickness of the membrane, and differ widely from the ordinary cerebral nerves in structure. They contain no white substance of Schwann, are not divisible into elementary fibrillæ, are nucleated and finely granular in texture, and are invested with a sheath of homogenous membrane." These nerves thus rather correspond with the gelatinous fibres, than with the ordinary tubular fibres of the trunks and branches of true nerves; and they are regarded by the authors as direct continuations of the vesicular matter of the olfactory bulb or ganglion. "Although these nucleated olfactory filaments lie in great abundance under the mucous membrane of the olfactory region, we have been quite foiled in our attempts to trace their ultimate distribution in the membrane, and the difficulty is attributable to their want of the characteristic white substance. Their elongated nuclei render the larger branches unmistakeable; but if these become resolved at last into fibrous elements, the nuclei cease to be distinct from those of the numerous nucleated tissues which they traverse." "We are averse from speculating prematurely on the meaning of anatomical facts; but as some hypothesis will intrude itself, we would venture to hint that the amalgamation of the elements of the peripheral part of the nervous apparatus in the larger branches, and probably in the most remote distribution, as well as the nucleated character indicative of an essential continuity of tissue with the vesicular matter of the lobe, are in accordance with the oneness of the sensation resulting from simultaneous impressions on different parts of this organ of sense, and seem to show that it would be most correct to speak of the first pair of nerves as a portion of the nervous centre put forward beyond the cranium, in order that it may there receive, as at first hand, the impressions of which the mind is to become cognisant."* It has also been remarked by the same excellent observers †, that on the septum narium and spongy bones bounding the direct passage from the nostrils to the throat, the lining membrane is rendered thick and spongy by the presence of ample and capacious submucous plexus of both arteries and veins, of which the latter are by far the larger and more tortuous. And they surmise, with much probability, that the chief use of these may be to impart warmth to the air, before it enters the proper olfactive portion of the cavity; as well as to afford a copious supply of moisture, which may be exhaled by the abundant glandulæ seated in the membrane. "The remarkable complexity of the lower turbinated bones in animals with active scent, without any ascertained distribution of the olfactory nerves upon them, has given countenance to the supposition that the fifth nerve may possess some olfactory endowment, and seems not to have been explained by those who rejected that idea. If considered as accessory to the perfection of the sense in the way above alluded to, this striking arrangement will be found consistent with the view which thus limits the power of smell to the first pair of nerves."*

The olfactive organ, in other air-breathing Vertebrata, corresponds with that of man in all the essential particulars of its structure; being a cavity opening anteriorly upon the face by the external or anterior nares, and posteriorly into the upper part of the pharynx by the internal or posterior nares. It may thus be considered as the entrance of the respiratory passages, which is dilated for the extension of the olfactive membrane; or, perhaps, it would be more correct to speak of it as a diverticulum from the commencement of the respiratory tube, since, as we have seen, the proper olfactive organ does not extend into that portion of the cavity which is placed in a direct line between the anterior and posterior nares. The development of the olfactive organ, as measured by the size of the olfactory ganglia and nerves, and by the extent of the surface over which these are distributed, varies greatly in different tribes; and details must be sought on this subject under the respective names of the classes and orders of vertebrata. The chief departure from the ordinary type is observable in the case of the Cetacea, in which the nasal cavity is almost entirely devoted to the purposes of respiration, and to the ejection of the water taken in by the mouth with the food. To animals which seek their prey in the water, an organ of smell, adapted to take cognisance of odorous emanations contained in the inspired air, would obviously be entirely useless; and it is probable that whatever olfactive power they possess is called into exercise by the passage of the water that is spouted through the nostril. The ordinary statement that the Cetacea are entirely destitute of olfactive ganglia and nerves, and that they must therefore be entirely devoid of the sense of smell, is true only of the *Delphinidæ*, or that division of the order which includes the dolphins and porpoises; for the *Balænidæ*, or proper whales, do possess olfactive nerves, although these are comparatively of small size; and in the *Manatidæ*, or herbivorous whales, which properly belong rather to the Pachydermata

* Physiological Anatomy and Physiology of Man, vol. ii. pp. 5—11.

† *Op. cit.* p. 3.

* Op. cit. p. 12.

than to the Cetacea, the olfactive apparatus is formed after the usual type.

In Fishes, however, the plan is altogether changed, the organ of smell being no longer connected with the respiratory passages, but disposed in a cavity peculiar to itself, which opens externally by anterior nares, but has no internal communication by means of posterior orifices.

No distinct organ of smell has yet been discovered in the Dibranchiate Cephalopoda; but in the *Nautilus*, a peculiar laminated organ, strongly resembling the olfactive organ of fish, has been considered by Prof. Owen as an olfactory apparatus. The inferior Mollusca would seem to be altogether destitute of special organs of smell; but as there is much reason to believe that some of them, especially the terrestrial Gasteropods, are guided to their food by its scent, it would not seem improbable that some part of the soft spongy glandular mantle, in which the entire body is enveloped, may be adapted to take cognizance of odorous emanations; or that in the air-breathing species, the entrance to the respiratory sac should be endowed with a low degree of this power.

There is ample reason to infer, from observations of the actions of Insects, that these animals possess the olfactive power in no inconsiderable degree; and yet no special organ for this sense has hitherto been satisfactorily made out. That many insects are guided to their food, to the proper nidus for their eggs, and to the opposite sex of their own species, and are even informed of the proximity of their natural enemies, by odorous emanations, can scarcely be doubted by any one who watches their habits, and who experiments upon their actions under a variety of circumstances. Thus, the flesh-fly will be attracted by the odour of decomposing meat, when this is completely hid from its sight; and will deposit its eggs on the envelope with which it may be covered. On the other hand, the same insect is deceived by the odour of the *Stapelia*, or carrion-flower, and is led to deposit its eggs in its petals. Again, many male insects will show that they are aware of the proximity of their females, when the latter are shut up in boxes, so as to he hid from their sight, and utter no sound. And in like manner, when a predaceous insect or spider is shut up in a box that gives a sufficiently free passage to air, the small insects on which it preys will manifest their alarm at its proximity, and will endeavour to make their escape. Some entomologists have supposed the seat of the olfactory sense of insects to be in their antennæ, others in the palpi, and others in the entrances to the air-tubes. No evidence can be adduced in favour of either of these suppositions that is satisfactory enough to prove it, and we have little other guide at present than *à priori* probability. In regard to the last of the three suppositions, however, it may be remarked that all analogy opposes the idea that the true olfactory apparatus should be thus scattered amongst the several segments of the body; and the experiments which appear to favour it really lead to no other conclusion than this, that acrid or irritating vapours, taken in through the breathing-pores, may excite reflex movements which seem destined to expel them, or to withdraw the body from them. Such movements resemble those of coughing and sneezing in man, which are excited through the nerves of common sensation, and not through the first pair; and they do not in the least indicate, therefore, that the sense of smell is in any way connected with the respiratory apparatus of insects, myriapods, &c. The use which many insects may be seen to make of their palpi, in taking cognizance of their food without actually touching it, suggests the idea that they are the true olfactive organs; and this idea is borne out by the fact, that these organs terminate, in the living state of many insects, in soft bulbous expansions, which shrivel up and become horny in the dead specimen, thereby obscuring their real character. On the other hand, many insects are furnished with soft membranous appendages at the base of their antennæ, which seem equally adapted to perform this function. And it is asserted by Dugès *, that insects whose antennæ had been cut off did not manifest the same cognizance of the neighbourhood of odorous substances, as did others of their kind whose antennæ had been left entire. It would seem not a very improbable supposition that, as the antennæ and palpi are organs of a similar class, the sense of smell may not be localised in one or other of them constantly; but that it may be assigned to one or the other, according to the modifications they may respectively require for the performance of their other offices. The same doubt exists in regard to the olfactive organ of the Crustacea. The manner in which crabs and lobsters are attracted by odorous bait placed in closed traps, makes it almost certain that they must possess some sense of smell; and the most probable locality of the organ would seem to be a cavity discovered by Rosenthal at the base of the first pair of antennæ.

As to the existence or absence of the sense of smell in the lower Invertebrata, nothing can be definitely stated.

Nerve of smell. — That the *first pair* of cranial nerves is the true *olfactive*, and that through it alone are the proper odorous emanations perceived, would seem a legitimate inference from the fact, that its development in vertebrated animals is constantly proportionate, *cæteris paribus*, to the acuteness of the sense; and that it is chiefly distributed to that part of the nasal cavity, which is most distinguished by the possession of this endowment. This inference is fully borne out by the facts supplied by experiment and pathological observation. The division of the olfactory nerves in animals evidently produces a complete destruction of the power of perceiving odours; although they are still affected

* Physiologie Comparée, tom. i. pp. 160, 161.

by irritating vapours. They do not immediately perceive these vapours, however, but seem indifferent to them at first, and then suddenly and vehemently avoid them as soon as the Schneiderian membrane becomes irritated. It was maintained by Magendie that the fifth pair in some way furnishes conditions requisite for the enjoyment of the sense of smell; this sense being destroyed, according to his assertion, by section of its trunk. His experiments, however, were made with irritating vapours which excite sternutation; and he inferred the loss of the sense of smell from the absence of the automatic movements which these vapours normally excite. This inference was altogether unjustifiable; since the experiments in question afford no proof that the power of perceiving *odours*, with which the excitement of automatic movements does not appear to be in any way connected, is destroyed by section of the fifth pair. A diminution in the acuteness of the true sense of smell, however, appears to be a usual result of paralysis of the fifth pair; but this is readily accounted for by the diminution of the normal secretion of the pituitary membrane, by which its surface is deprived of the moisture that is necessary for the exercise of its sensory powers. The difference in the endowments of the first and fifth pairs of nerves, and the speciality of the former, are further marked by the result of mechanical irritation of their trunks and branches. Such irritation of the first pair excites no muscular movement, either direct or reflex, and it produces no indication of pain. On the other hand, irritation of the nasal branches of the fifth pair is obviously attended with violent pain, and excites various automatic muscular movements. Lastly, it has been found that in cases of deficiency or loss of the sense of smell, some abnormal condition of the olfactive nerves or ganglia has existed; and the same kind of change has been discovered in cases in which *subjective* sensations (*i. e.* sensations not originating in external objects) had existed during life.

Conditions of the exercise of the sense.—The first condition requisite for the exercise of the sense of smell, is the contact of the odoriferous medium with the olfactive surface. This may be favoured or prevented by a variety of circumstances. Thus, odours are more rapidly transmitted by air in motion than by air at rest; but they only proceed in the direction of the movement: and hence animals possessed of the keenest scent, which would be alarmed by the presence of a human or other foe a mile off on the windward side, may be approached within a short distance on the leeward, when a fresh breeze is stirring. The odoriferous medium must not only be brought *to* the nose, but it must be introduced *within* the olfactive cavity. This is usually accomplished by the ordinary movement of inspiration, which draws a current of air through the nose; but as the current chiefly passes through the lower part of the nasal cavity, to which the olfactive nerve is very sparingly or not at all distributed, the full use of the sense of smell is not thus gained. It is only by making a series of short and *quick* inspirations,—the effect of which seems to be, to empty the *whole* nasal cavity of the air it previously contained, and thus to cause the newly-inspired air to pass forcibly into its upper part, instead of merely streaming through the passage between the anterior and posterior nares,—that we employ our olfactive powers to the best advantage. This movement, combined with the direction of the nostrils towards the source of the odour, and with the dilatation of their orifices by the muscles adapted for that purpose, constitutes the *active* exercise of the sense, which may be termed *scenting*. This bears the same relation to ordinary smelling, as feeling bears to touch, listening to hearing, or looking to seeing. The effect of the sensory impression on the mind is further heightened by the attention which is bestowed upon it; and it does not seem improbable that the sensation itself is rendered more acute by an increased determination of blood to the olfactive surface when it is being thus actively employed. On the other hand, the use of this sense may be prevented, not merely by the closure of the nares, anterior and posterior, so as completely to exclude the odoriferous medium, but also by simply refraining from drawing air into the nasal cavity. If we breathe through the mouth only, closing the posterior nares by means of the velum palati, we may avoid being affected by odours even of the strongest and most disagreeable kind; for the nasal cavity being already filled with air, there is no room for the entrance of the odoriferous atmosphere from without; and it may thus be long before the odorous particles come into contact with the olfactive surface.

It is, of course, an essential condition of the exercise of this sense, that the whole nervous apparatus, which forms the essential part of its organ, should be in a state of integrity; and that a free circulation of blood shall take place through the olfactive portion of the pituitary membrane. But, in addition, it is requisite that the epithelial and mucous covering of the membrane be in a normal state. If the surface be too dry, the odorous particles cannot undergo that solution in the fluid in contact with the sentient extremities of the nerves, which seems necessary for the production of an impression on them. On the other hand, when the secretion is too abundant, it interferes with its contact in the opposite manner. And thus it happens that the sense of smell is blunted, both in the primary and secondary stages of an ordinary cold, by the disorder of the secreting surface, independently of the effect which the disturbance of the circulation may have upon the functional power of the olfactive nerve.

Purposes of the sense.—When we take a comprehensive survey of the animal kingdom, we at once perceive that the most *general*, and therefore the most *essential* purpose of the sense of smell, is to make known the presence of food, to indicate its direction and thus to guide the animal towards it, and to aid in the discrimination of its qualities. We *always* find the olfactive organ placed in the neighbourhood of the mouth; its connection with the respiratory apparatus is by no means so constant. In air-breathing vertebrata, whose olfactive cavity opens into the pharynx, the sense of smell largely participates in that of taste (see TASTE), being the means by which we take cognisance of the *flavours* of sapid bodies introduced into the mouth. Of the importance of this sense in directing animals to their food, it is needless to multiply instances; but we may remark that, from observation of the actions of the human infant, we are well convinced that it is rendered cognisant by smell of the neighbourhood of its nurse, long before it recognises her by sight, and that this sense is its guide in seeking the source of its nutriment. How purely instinctive this action is, — that is, how completely independent of all experience, and entirely dependent upon the provocative sensation, — is well shown by the experiment of Galen, who placed a kid, just dropped, near three vessels, one filled with milk, another with honey, and another with wine; after smelling at all three, it presently began to drink the milk. It would seem to be by the information conveyed through their smell, that bees are induced to fly to pastures at a great distance from their hive; and it would not seem improbable that the sense of *direction*, which is so remarkably displayed by many animals, is the result of the acuteness of their olfactive power. Whilst the chief use of smell to the carnivorous tribes is to guide them to their prey, the herbivorous races, whose food is constantly within their reach, are warned by its means of the neighbourhood of their enemies. The sense of smell is subservient to defence in another way; being the means by which the fœtid scents, emitted by many animals under the influence of alarm, deter their enemies from further pursuit. In nearly all animals, the sexual secretions are more or less odorous; and these would seem to be intended, not merely to contribute to make the sexes aware of each other's proximity, through the sense of smell, but also, in many instances, to serve as a provocative to sexual desire. The odours which are attractive to animals are usually related either to their food or their sexual instinct; but there are cases in which animals seem to delight in odours which have no such relation: thus, cats seem to revel, as it were, in the odour of Nepeta (catmint) or Valerian.

In the air-breathing vertebrata, the sense of smell is, as it were, the sentinel of the respiratory organs, having for its office to take cognisance of the aeriform fluids which enter them, and to give warning of such as are injurious. The contact of *irritating* matters, however, is perceived (as already stated) through the general sense of feeling, not the special sense of smelling; and it is through the fifth pair that the act of sneezing is excited, the purpose of which is to expel such particles from the nasal cavity. The distinction is well seen in some air-breathing invertebrata, whose organ of smell is seated in the head, whilst the impression of irritants on the respiratory surface, exciting reflex movements for the purpose of avoiding or expelling them, is made through the stigmata. Thus M. Dugès relates* that if the stigmata on one side of a decapitated Scolopendra be exposed to an irritating vapour, the body will be immediately flexed in the opposite direction; and that if the stigmata on the opposite side be then similarly irritated, a contrary movement will occur; whilst by exposing the anterior stigmata on one side, and the posterior on the other, to the same irritation, the body will be bent into the form of the letter S.

In man, the sense of smell is not ordinarily so acute as it is in many of the lower animals; yet it is very possible that it may be capable of taking cognisance of a greater *variety* of odours. In the selection of his food, it is to him by no means the infallible guide that it seems to be in many other races; for it not only gives no warning, in many instances, of what is noxious, but renders certain poisonous substances (as, for instance, those charged with prussic acid or the essential oil of almonds) positively attractive. So, again, in regard to the respiratory organs, whilst it gives warning of the presence of certain gases and emanations which are injurious, it takes no cognisance of many others which are not less hurtful. In the ordinary conditions of civilised life, man is not dependent upon his sense of smell for many of the ends which it answers in other animals; hence this sense is altogether subordinate to others, and the want of it is not usually attended with any great inconvenience. But the case is far different among savage tribes, to whom it is as important as it is to other animals in a state of nature, and in whom it seems to acquire, by the constant habit of attention to its indications, a similar acuteness. Thus, it is stated by Humboldt that the Peruvian Indian, in the middle of the night, is informed of the proximity of another individual by his smell, and can distinguish by his smell whether the stranger be an European, an American Indian, or a Negro. It has even been asserted that some other savage tribes of mankind are enabled to follow a track by the scent of the footsteps, like the bloodhound. The sense of smell, moreover, usually acquires great acuteness, when, from deficiency of the other senses, its indications become the chief or only means of recognising bodies not in immediate contact with the individual. Thus, in the well-known case of James Mitchell, who was deaf, blind, and dumb from his birth, it was the principal means by which he distinguished persons, and enabled him at once to perceive the entrance of a stranger. Mr. Wardrop gives the following curious account of the mode in which he exercised this sense, and of

* Op. cit. tom. i. p. 162.

the information which he derived from it:—"There were some people whom he never permitted to approach him, whilst others at once excited his interest and attention. The opinions which he formed of individuals, and the means he employed to study their character, were extremely interesting. In doing this, he appeared to be chiefly influenced by the impressions communicated to him by his sense of smell. When a stranger approached him, he eagerly began to touch some part of his body, commonly taking hold of the arm, which he held near his nose, and after two or three strong inspirations through the nostrils, he appeared to form a decided opinion regarding him. If this was favourable, he showed a disposition to become more intimate, examined more minutely his dress, and expressed by his countenance more or less satisfaction; but if it happened to be unfavourable, he suddenly went off to a distance with expressions of carelessness or disgust. When he was first brought to my house to have his eyes examined, he both touched and smelled several parts of my body; and the following day, whenever he found me near him, he grasped my arm, then smelled it, and immediately recognised me, which he signified to his father by touching his eyelids with the fingers of both hands, and imitating the examination of his eyes which I had formerly made." We learn from the same account, that in selecting his food, he was always guided by his sense of smell, for he never took anything into his mouth without previously smelling it carefully. He always recognised his own clothes by their smell, and refused to wear those which belonged to others.

Sometimes the peculiar acuteness of this sense is restricted to a particular odour or class of odours, these usually proceeding from objects for which there is either a special fondness or a particular aversion. Thus, a gentleman blind from birth, who had an unaccountable antipathy to cats, so that he could never endure the presence of one in his apartment, one day, when in company, suddenly leaped up and exclaimed that a cat was in the room, begging his friends to remove it. It was in vain that, after careful inspection, they assured him that he was under an illusion. He persisted in his assertion, and his agitation continued; and on the door of a small closet being opened, it was found that a cat had been accidentally shut up in it.

With such unequivocal proofs of the acuteness of the sense of smell which may exist in the human subject, the statements made respecting the extraordinary exaltation of the faculty in various forms of somnambulism become less incredible; and the author is fully satisfied, from his own observations upon individuals *hypnotised* by Mr. Braid (see SLEEP), that this exaltation may certainly take place in regard to the sense of smell. In one instance, a glove being placed in the hand of the hypnotised subject, he found out the owner of it without difficulty, from amongst more than sixty persons, scenting at each of them, one after another, until he came to the right individual. And in another case, the owner of a ring was in like manner unhesitatingly found out from amongst a company of twelve.

The information conveyed by the sense of smell is restricted to the *quality* and *intensity* of the odour, and to some general notion of its *direction*. This last, indeed, is rather derived from a comparison of its relative intensity when the face is turned towards different sides, than from any more direct information as to locality furnished by the organ itself. The absence of any consciousness of the part of the olfactory surface specially affected by the impression,—so that, unless the experiment be made, we know not that we are constantly exerting the sense on both sides, the double sensation being perceived as a single one,—is attributed by Messrs. Todd and Bowman*, with much probability, to the peculiar plexiform arrangement of the fibres of the olfactive nerve, and to the want of the isolation usually effected between the fibres by the white substance of Schwann.

Various classifications of odours, founded upon the impressions which they make upon the sense of smell, have been proposed; but they are all liable to the objection, that there seems to be more of individual diversity in regard to the character of olfactory impressions, than with respect to those of any other kind. Many odours, by some persons thought intolerable, are very agreeable to others; thus, assafœtida is known amongst some by the name of "devil's dung," whilst by others it is spoken of as "food for the gods." It was commonly employed by the ancients as a condiment; but the individuals who thus relish it in our own country certainly constitute the exceptions to the mass. So, again, the *fumet* of game, so highly valued by the epicure, is disagreeable to most persons who have not been trained to appreciate it. On the other hand, the aroma of certain flowers, which is peculiarly agreeable to most persons, is by no means so, or perhaps the reverse, to others. Thus, Müller remarks that the smell of mignonette is to him only herb-like; whilst the flower of *Iris Persica* has been pronounced to be of pleasant odour by forty-one out of fifty-four persons, by four to have little scent, by eight to be without all odour, and by one to be ill-scented.†

It more frequently happens, in regard to odours and savours, than with respect to other sensory impressions, that habit renders that agreeable, and even strongly relished, which was at first highly repugnant.

(*W. B. Carpenter.*)

SOFTENING and INDURATION (*Ramollissement et Induration*,—*Endurcissement*, Fr., *die Erweichung und Härtung*, Germ.) are terms used to express a pathological or physiological diminution and increase, of the consistence of the body or its parts.

* Op. cit., p. 12.

† Arnold's Physiology, vol ii. p. 561.

Softening and induration in a physiological sense, refer to those changes which occur in the density of tissues and organs during their development, growth, and decay ; whilst, in a pathological sense, they refer to alterations in the normal consistence, with or without actual molecular change.

In order to be able to distinguish morbid alterations of cohesion, from those which occur in the natural course of things, it is necessary to be well acquainted with the power exercised by age, sex, and idiosyncrasy, in modifying the density of the tissues.

Softening and induration are but relative terms, the standard of consistence is constantly varying, both as regards the whole body, or as regards organs and tissues. In the fœtal state all the tissues are soft, and contain large quantities of fluid ; as development proceeds, so do the parts gradually become hard, not all equally so, for certain tissues remain permanently soft in comparison to others, which rapidly increase in density. After birth, the hardening processes still continue, and it is not until the age of puberty is passed, that all the tissues have attained their highest stage of development. But the process of natural hardening is interfered with, or retarded, by peculiar idiosyncrasy and by the influence of sex and occupation; the general firmness of the tissue of an athlete is greater than that of those, who, although in perfect health, happen to lead inactive and sedentary lives ; it is greater as a general rule in the male than in the female sex, and in the sanguineous than in the lymphatic temperament.

As old age comes on, changes in the consistence of the tissues occur, which are produced by the natural decay to which all organized matter is subject ; thus the cellular tissue, the serous and mucous membranes, the muscles and tendons, bone, the brain and nervous system, and particularly the uterus and ovaries, sometimes acquire a degree of hardness, equal to that which is known to be produced by certain diseases.

Finally, after death the whole organism is affected by forces, which had little or no influence upon it during life ; the tissues are subjected to the macerating influence of their fluids, which may also act chemically upon them. In the natural course of things, softening and putrefaction, and disorganization of the ultimate atoms of our body occur, before they are fitted to be assimilated into other organized structures ; this decay increases as time progresses, and is enhanced by a high state of temperature and exposure to the air. After death, hypostatic congestion of the cellular tissue simulates the appearance that this structure frequently presents, when affected with inflammatory softening ; and the macerating effects of the fluids, which had no such influence during life, are seen in the brain and spinal cord ; whilst the alimentary mucous membrane suffers softening and disintegration from the peculiarities of the fluid usually secreted by it. By recognising then the normal alterations of cohesion, and those arising from post mortem causes, the attributes of morbid softenings will become perfectly apparent.

Softening and induration are said to exist without any structural change ; such is not generally the case, indeed it is exceptional, and were such a state only to be properly termed softening and induration, many of the most important and interesting pathological facts would be unaccounted for. Softening and induration are produced by a variety of causes, and frequently co-exist in the same organ, or one may supervene on, or cause, the other.

Both softening and induration may be produced by inflammation leading, on the one hand, to effusion of serum and pus, and on the other to the deposition and subsequent contraction and hardening of coagulable lymph ; the one appears to be the result of acute, and the other of subacute, inflammatory action. Active sanguineous congestion produces in some organs the sensation of diminished consistence, whilst in others, especially in those surrounded by a dense fibrous tissue as the testicle, hardening results. In softening, the effused product of inflammation, appears not only to break down the structure by infiltration, but also by its pressure to impede the usual nutrition of the part.

The softening of an organ, induced by inflammatory action, is frequently confined to one of the component tissues, especially to the cellular tissue ; the readiness with which the serous envelope may be stripped from off a parenchymatous organ, depends more upon the subserous cellular tissue, than upon the other structures ; and, in like manner, the softness of a whole organ is often assignable, rather to the deficient tenacity of the membrane which unites its lobules, than of the proper tissue.

Softening may be produced by causes totally differing from those produced by inflammation ; it may depend upon a deficiency or perverted state of the blood, and an anæmic state of the general system. For instance, in white softening of the brain, the arteries, which ought to have sufficiently nourished the affected parts, fail to do so on account of their being blocked up, more or less, by abnormal deposits. In certain softened states of the spleen, the blood contained in its parenchyma loses its consistence, and becomes more fluid than natural, from a perverted state of its constitution ; and the flabby muscles and general loss of tone of anæmic subjects are notorious.

In scrofula, the perverted state of the general nutrition produces softening of peculiar tissues, for instance, of the bones ; and in the cancerous cachexia like effects occur.

Long continued functional inactivity, for instance of the muscles of an extremity stricken with paralysis, tends to produce softening ; and pressure, in certain instances so interferes with the nutrition of a part as to diminish its cohesion. Fatty deposit in the ultimate cells of tissues and organs, renders them soft and flabby; as will also infiltrations of certain morbid adventitious products. The compound granule cells found in acute softening of the brain, and mixed with pus in other situations, are described in the article on ADVENTITIOUS PRODUCTS. Softening may be accompanied by atrophy, or by hypertrophy, which is generally produced by simple congestion; or no alteration of bulk may occur. Three degrees of softening are recognised:—in the first, the softened tissue is still solid, but it breaks down and tears and can be perforated with ease; in the second, all solidity is gone, nothing but a pultaceous semi-fluid mass is found; and, in the third degree, the tissue is broken down and diffluent.

Softened parts may retain their natural colour, or may be paler, or may have an increase of colour. Softening, without any change of tint, occurs in mucous and serous membranes, in the brain, heart, liver, and uterus. All post mortem softenings are of this kind, except where the colouring matter of the blood has tinted the effused fluids.

In certain softenings of the brain the affected parts are much paler than usual, being of a dead white colour; there is a diminution in the quantity of blood usually present in the diseased parts; a like decrease of colour is found in other softenings.

Generally, however, softening is accompanied by reddening, or by an increased colour; the tints may vary from a bright vermilion to a brownish red, and may be seen as grey, almost black, and, occasionally, are yellow. These varieties of colour depend upon the amount of blood usually existing in the softened tissue, and upon the degree of congestion. The redness of softened tissues is occasionally partial, and merges into lighter tints as the tissue becomes harder. Partial effusions of blood, or highly injected vessels, are commonly found in red softenings.

Induration, generally speaking, is to be regarded as a symptom of previous or coexisting diseased states; its physical condition varies much in its nature, in the same or in different tissues, as proved by microscopical, mechanical, and chemical analysis; and both observation and experiment tend to prove, that it is produced by causes of a very opposite kind.

Changes in the amount of fluid destined for the nutrition of a part, frequently give rise to induration; an increased quantity of blood and a consequent increased deposit of solid structure, produce simple induration of many organs, which are liable to variations in the quantity of blood they may contain, for instance, the brain and spinal marrow, the cellular and muscular tissues; also of denser structures, as bone, in which the induration is occasionally extreme, and in fibrous tissues; they produce also hardening of the lymphatic glands and of the salivary glands. The brain has been found to be increased to twice its natural density and consistence. Muscular, fibrous, and cellular tissues, become so hard, as to give out a grating sound when cut; and the walls of some hollow organs, naturally soft and flaccid, acquire such a degree of firmness, that they preserve, when empty, a globular or cylindrical form, and spring up with considerable force after sudden pressure; and parts of bone acquire that degree of hardness, which has been termed eburneoid induration. An increased quantity of the usual fluids of nutrition frequently gives rise to induration, differing from that just described, in not being attended by deposition of solids. The accumulation of blood in the vessels of the lungs and spleen, the result of congestion, produces, sometimes, a great degree of hardness and density of these organs. Diminution of the quantity of the same fluid, especially when there is also a compressing force, is also followed by an increase of consistence, and, generally, by a decrease in bulk of certain organs; in pleurisy, for instance, dense false membranes, by their pressure, compress the lung into a small space, and its tissue becomes indurated from simple approximation; for, on the removal of the compressing agents, the lung can be inflated.

The inordinate increase and accumulation of the secretion of certain organs, as the mamma, testis, gall bladder, and kidney, produce a degree of hardness, sometimes equal to that of dense tumors, arising from the incompressibility of the fluids themselves, and the state of condensation of the walls of the organs in which they are accumulated.

Effusions of serum and blood into the tissues from mechanical causes produce great distension and induration; such is the case in the œdema of the cellular tissue of the extremities in dropsy; effusion of serum into the intermuscular cellular tissue produces hardening. Pulmonary apoplexy and ecchymosis in various organs, from a mechanical impediment to the return of blood to the heart, have a like effect.

But inflammation of a sub-acute form is the great cause of induration, from the effusion of serum and coagulable lymph; the former of which is absorbed, and the latter becomes "induration matter," whose properties are described under the head of ADVENTITIOUS PRODUCTS; this last product produces induration on account of its being actually denser than the tissues into which it is effused, and, also, by its compressing power, for it has the peculiarity of contracting and becoming hard after its deposition. Certain morbid states of the blood, occasionally produce indurations of certain organs.

The changes of form, with which induration may be connected, are numerous; none may, however, occur; the bulk also of indurated structures varies; it may remain unchanged, but, generally, it is increased, and more rarely, decreased.

The colour of indurated parts, is generally different from the normal tint; sometimes, owing to diminished vascularity, and to the presence of induration matter, it may be pale; at others, owing to increased vascularity, and the state of the fluids of the tissue, and the presence of effused or infiltrated matters, it may be bright or dark red, grey, yellow, and sometimes almost black.

Induration presents several degrees of resistance to pressure or to the knife ; much depends on the ordinary cohesion of the affected organ. Generally speaking, the first degree is characterised by a slight increase in the resistance to pressure; the second finds the tissue denser, cutting with a cracking noise; and the third comprehends increased cohesion, amounting to a cartilaginous or bony hardness.

Softening of the brain may be ascribed to inflammatory action, or to a defective state of the circulating apparatus of the organ; it may be an effect of a defective or perverted state of the body generally, and it is frequently caused by post mortem agencies. Now these four varieties of softening, although, as regards their external appearances they have much in common, differ considerably from each other, each having peculiar attributes. The first and second varieties are generally found in the most, and the third in the least, vascular parts of the brain. Post mortem softening occurs, for the most part, in the immediate neighbourhood of the ventricles, is usually very diffused, is found on both sides at once, and is, of course, never preceded by symptoms.

Softening of the brain may be partial or general, and may present various degrees: the least change of consistence is only to be recognised by the microscope; in a more advanced degree the softening is obvious to the unassisted senses, at first to the touch and then to the eye, the diseased part being pultaceous, and readily removed by a stream of water, a cavity surrounded by healthy structure being made evident.

In a more advanced degree still, the cerebral substance instead of being pultaceous is quite diffluent, and occasionally a perfect solution of continuity is found. The softened portion of brain presents various alterations of colour. In inflammatory softening, the colour mainly depends upon the previous quantity of blood in the part; it may be of a deep red colour, with or without effused clots of blood, and frequently merges at the edges into at first a deep, and then a pale, yellow colour. Sometimes the yellow colour is central and the reddened portion external, resembling a collection of pus, so much so that Lallemand described it as such.

A dull red ochre colour with more or less hardening in the neighbouring structure, is indicative of chronic disease of long standing; as is also a chalky milk appearance, and a bright vermilion, of a recent effusion of blood into a previously softened part. In commencing softening, a diffused blush, with or without spots of blood, is generally found. A deep grey colour and fawn and dirty white tints accompany inflammatory softening, but much more frequently that which is produced by a deficient supply of blood.

No alteration of colour takes place in post-mortem softening.

These distinctions of colour indicate no essential differences, as far as structure is concerned, for all coloured softenings may present the same histological characters. As a general rule, the red varieties are indicative of acute inflammation, yellow of subacute, and white or grey of deficient nutrition of the affected part; but this rule is by no means invariable.

Universal softening of the brain, accompanied by a smell of sulphuretted hydrogen, is found in children suffering from general debility, and occasionally in infants stricken with induration of the subcutaneous cellular tissue.

Softening from a defective state of the circulatory apparatus is found, for the most part, in persons advanced in life, and constitutes what is termed *white softening*. It depends on the presence of osseous, cartilaginous, or atheromatous matter in the walls of the arteries, nearly or quite blocking up their entire caliber, and affecting vessels of all sizes. It may supervene upon occlusion of the common carotid from ligature, and, indeed, upon any circumstance retarding or diminishing the quantity of blood to the brain; intense inflammation may disorganise the vessels, carrying blood to a remote portion of the brain, and thus cause softening; or a severe blow, or the presence of a tumor of greater or less density and magnitude, may act in the same manner.

The very fact of adventitious products being found within the arteries, hints at a perverted state of the brain and system generally; absorption does not progress in the diseased portions of the brain, which, having lost their supply of blood, are in a state analogous to that of an extremity attacked with gangrena senilis.

The softening of the brain which is produced by post mortem agencies is of very frequent occurrence. It may exist alone, or may complicate the other varieties, and is caused by the decomposition natural to organised bodies after death, or by the infiltrating action of fluids, which, either during life or in the agony of death, were effused into the ventricular cavities, and sub-arachnoid spaces.

Softening of the spinal cord is of not uncommon occurrence. It presents the same characters as those pertaining to the like affection of the brain, is produced by the same causes, and offers the same pathological characters. Softening of the whole cord may occur, but most frequently parts of it only are affected; it is found softened most frequently in the lumbar region, and not unfrequently in the cervical.

Induration of the brain may be general or partial, and presents three degrees of consistence. In its first degree, the affected part is nearly of the consistence of a brain which has been left some time in dilute nitric acid; in the second degree, the indurated part is of a cheesy, and in the third of a waxy, fibro-cartilaginous hardness. General induration affects either the whole or the greater part of the brain: the degree of hardness never exceeds the first variety. The induration is not always equal throughout the whole of the parts affected, the central medullary parts usually exhibiting a higher degree of it than the grey substance. A section of the indurated portions generally presents increased vascularity, in the usual speckled and striated form; yet the reverse is occasionally observed, the brain being preternaturally white.

Induration of the spinal cord may be general or partial. Billard found a spinal cord in a child of a few days' old, which, without the membranes, supported a pound weight. In partial induration, the white, and not the grey, matter is usually affected. For further remarks on the softening and induration of the spinal cord, see the article NERVOUS CENTRES (Abnormal Anatomy).

Softening of the heart occurs as a diminished state of the cohesion of the muscular structure. It is a rare disease, and is produced by very opposite causes; from inflammation, from a defective state of the nutrition of the organ, with or without general anæmia, and from a perverted state of the nutrition of the muscular and cellular elements. The heart when softened collapses on itself when empty, tears with the greatest facility, and breaks down with little pressure, the finger perforating its substance and penetrating into its cavities with great ease. Its colour varies, being sometimes deep red and violet, at others dirty white, and occasionally of a faint yellow hue. Softening of the heart may be general or partial, superficial or deep-seated; it may be confined to the walls of a particular cavity, or to the ventricular septum, or it may occur in small patches, disseminated in the midst of the muscular substance. Softening of the heart may coincide with hypertrophy of its walls, or a dilated state of its cavities, and Hope found it in a case of angina pectoris.

When found as a sequel of carditis, the softening is of a dark tint, the fibres are dark from the whole heart being gorged with venous blood, soft and loose in their texture, being easily separable, and compressed with facility between the fingers. When accompanying chronic carditis and co-existing pericarditis, the white colour predominates, sometimes being nearly superficial, and attended by pericardial and sub-pericardial effusion.

The yellow-coloured softening is found in cases of local and general anæmia, in malignant fevers; and it sometimes has an inflammatory, as well as merely cachectic origin. An abnormal deposition of adipose tissue in the cellular structure of the heart, produces softening by affecting the nutrition of the muscular fibres, which suffer also from the state of system peculiarised by the above deposition.

Induration of the heart is said to follow carditis, and appears to be produced by the effusion of lymph into the cellular tissue, around the muscular fibres and beneath the serous membranes; by its contraction and subsequent hardening, it may pass into a substance almost equal to bone in hardness.

It may exist in any part of the organ, the whole of the apex and the columnæ carneæ of the left ventricle were found indurated in one case, and in another the walls of the ventricles were tough, did not collapse, and emitted on being struck, a ringing hollow sound. We sometimes find partial softenings and indurations in the same heart.

Softening of the lungs generally depends upon the presence of effused products of inflammation; for instance, in the engorged, hepatised, and suppurative stages of acute pneumonia. It is worthy of remark, that, although in the hepatised stage the lungs are heavier, contain less air, and appear denser, still they are more fragile, and on being pressed by the finger break down. The more acute and recent the inflammation, the greater the softening. When we press a healthy lung with the finger, it gives to the touch on account of the elastic state of the tissue; but this is lost, and an unusual resistance, easily broken through, is produced by the loss of air, and the presence of lymph, compound granule cells, serum, and an abnormal quantity of blood.

In the third stage of pneumonia, softening is produced by the alterations in the effused products; lymph, for instance, is converted into a yellow friable matter, which subsequently becomes pus. In typhoid pneumonia the softening is great, even in the first or congestive stage.

Softening of the lung may be produced by an insufficient supply of blood. A part of a lobe may be so indurated, that the vessels and bronchial tubes passing through it become blocked up; the tissue which ought to have been supplied by these becomes at first soft, and finally gangrenous.

Induration may occur in any part of the lung, it may affect simply the bronchi and the tissue in their immediate neighbourhood, or the interlobular cellular tissue and the parenchyma may suffer.

The bronchi after long continued and repeated attacks of inflammation are found in a more or less indurated state, the hardening being generally in the outer cellular coat, and the cartilages of the larger tubes may become as hard as bone. The lung in the vicinity is generally denser than it should be.

The interlobular cellular tissue may be hardened at the same time as the lobules, or separately; it becomes more apparent than usual, and acquires a density occasionally resembling fibro-cartilage, and sometimes exercises so compressing an influence on the lobules, as to obliterate them.

But it is as a sequel of inflammatory action of long duration, that hardening of the whole or part of a lobe is found; the vesicular structure first suffers, the air vesicles are obliterated, and, often enough, the bronchi and blood-vessels of a certain magnitude.

Such portions of lung are dense, not at all friable, possess a peculiar crispness, and contain little or no air.

The colour of an indurated lung may be light or dark grey, or brown, and rarely pale.

A section of a piece of indurated lung shows the circular apertures of the bronchi and larger blood-vessels, surrounded by a dense tissue in which no vesicular structure is seen. The fibrinous dense lymph which produces these changes frequently becomes the nidus for tubercular deposit.

Partial indurations are found around tubercular cavities and abscesses, and around collections of miliary, or of larger tubercular masses.

In certain obstructive diseases of the heart the circulation in the lungs is so impeded, that effusion of blood, constituting pulmonary apoplexy, or effusion of lymph, producing general increase of density of the whole lung, may occur.

Long continued pressure by a pleuritic effusion, has the effect of rendering the lung nearly solid and impervious to air.

In treating of alterations in the cohesion of *mucous*, *serous*, and *articular membranes*, it is necessary to premise that they consist of a basement membrane sustaining epithelium cells and supported by sub-basement areolar tissue in which vessels, nerves, and absorbents, are found.

The nutrition of the basement membrane and the proper development of the epithelium cells depend upon the amount and health of the fluid parts of the blood supplied to them by the capillaries of the sub-basement tissue. It is evident that any morbid state of this tissue will influence the integrity of the basement membrane and the epithelium cells; and it is known that, for the most part, physical alterations of these last depend upon such morbid states, and that these changes are most likely to happen where the cellular structure is loose and considerable in amount.

Softening has been found in all serous and fibro-serous membranes, and may be produced by inflammatory action and by a defective and perverted state of the general nutrition of the body.

The *lining membrane of the heart* is frequently softened, being at the same time redder and more vascular than usual. It is occasionally so soft as to peel very readily from the muscular structure; a like state of the *pericardium* exists with effusion of pus into its cavity. Softening of the *internal membrane of the venous system* is found of either a deep red or pale colour; the tissue is very lacerable and breaks down into a pulp under the scalpel; it may be caused by phlebitis, by the pressure of a considerable column of blood, especially when the valves have been obliterated; and is found in cases of malignant fever, scurvy, and whenever the fluids are greatly altered. Post mortem softening is frequent enough to raise our suspicions, and great allowance must be made for the macerating and colouring properties of the blood.

Chronic softening of the *internal membrane of arteries* is occasionally found; when so affected the serous tissue is easily lacerable, and such solutions of continuity are determined by causes, which ought in health to have no influence. Portions of the interior lining membrane may be found retracted and rolled up within the canal, so that with the effusion of lymph which generally occurs at the same time, and the consequent coagulation of a small portion of blood, the artery may become completely obstructed and obliterated in a part of its course. Occasionally, the arteries of the upper and lower extremities become thus affected in succession, on the employment of the slightest exertion, indicating a very extensive affection of the nutrition of the arterial system. We find, in cases of anæmia, and where atheroma is being deposited, considerable diminution of the general tenacity of the large vessels.

Softening of the *arachnoid*, *peritoneum*, and *pleura* is generally found where there is effusion of pus, or blood into the sub-basement tissue; it rarely occurs when lymph is thrown out into the serous cavity, but seems to be a more advanced phenomenon of inflammation, or, rather, is produced by inflammation of a more intense and destructive character.

Dalmas ascribes nearly all serous softenings to diseased states of the subserous cellular tissue, and we find constantly that on account of the altered state of this cellular structure, the peritoneum and pleura may be stripped off large spaces of the parts they cover; it is notorious, that in the pelvis sero-sanguineous effusion into the subserous cellular tissue, and consequent lacerability of the serous membrane, frequently occur. Pulpy degeneration of synovial membrane is a kind of softening with a perverted state of the nutrition of the tissue.

Softening of mucous membranes is generally produced by inflammatory causes: it is most frequently noticed, and is best studied, in the alimentary canal, part or the whole of which may be affected; it is most frequently observed at the end of the ilium, in the depending portion of the colon, and in the cæcum; in the right and left hypochondriac regions, and in the sigmoid flexure.

Softening of the mucous membrane in general, or of any one or more of its elements in particular, presents various degrees. In the first degree, the mucous membrane, instead of possessing that degree of cohesion which permits of its being detached from the submucous tissue, breaks as soon as it is seized between the fingers or blades of the forceps; in the second degree, the edge of a scalpel, or the finger, pressed lightly over its surface, converts it into a soft and somewhat opaque creamy looking pulp; and, in the third stage, it is so soft that it is removed with ease by a slight stream of water. In this stage portions of the mucous membrane are found partially or entirely destroyed, and having been removed by the fluid contents of the stomach or intestines, as the case may be, during life, the submucous cellular tissue is thus found destitute of its natural covering. It is in this manner that various forms of softening are produced, as irregular or circular patches of various sizes. It is important to notice this circumstance, for, when the softening is limited to the glandulæ solitariæ, as is frequently the case in dysentery, it might be overlooked; these bodies being very small, and their entire destruction by softening being often unaccompanied by any obvious alteration of the mucous membrane itself, the seat and nature of the intestinal affection might not be ascertained, were it not for the presence of a number of minute circular patches, which, when narrowly examined, are found to be the result of softening of these follicles; for it often happens that enlarged follicles are seen intermixed with the patches, and which, when a scalpel is carried over the surface of the mucous membrane, break down or are removed, and thus other patches are formed similar to the former. These circular patches, which have the submucous tissue for their base, are often described as ulceration of the mucous membrane; but in all cases of doubt, the scalpel, used as above, will enable us to determine their nature.

Softening of the mucous membrane in the form of stripes and bands, has been described with great care by Louis, and has been much insisted upon as a characteristic of inflammatory softening; but Carswell has proved its origin from post mortem causes.

Softening of the mucous membrane of the digestive organs, may present various degrees of redness, or it may be quite pale; the redness may be confined to the softened part, or it may extend to the neighbouring parts at the same time; or the latter may be red and the former pale.

The redness of the softened membrane may vary from a light or a dark red to a brownish or purple; varieties of colour the value of which it is by no means easy to estimate, inasmuch as the quantity of blood in an inflamed tissue cannot be taken as a measure of the degree of inflammation which had caused the accumulation of this fluid.

The pale softening presents also some variety of tint. The softened tissue is either of a pale greyish or yellowish grey tint, being little altered from its natural colour; or it may be paler than natural, when it generally presents a milky aspect, owing to the colour of the submucous tissue being seen through it.

The pale softening is found in pthisis, in tubercular disease of the mesenteric glands, and in any disease accompanied by great emaciation.

Softening may be accompanied by thickening of the submucous tissues, and may precede and surround ulcerations.

The inflammatory softening of the other mucous membranes resembles as closely as possible that which has been described; it is not however so frequently complicated with post mortem effects, nor does it so often occur, except in the œsophagus, stomach, and intestines from the action of irritant poisons, which produce it either by their direct action, or by inducing and modifying inflammation.

Softening of mucous membranes from post mortem causes, is of great importance as a pathological fact, and may be produced by the action of the secretions of the membrane itself, or by putrefaction. This last cause is of doubtful efficacy; it is not likely to be met with in post mortem examinations, made at a reasonable period after death; it may however suffice to cause complete decomposition, when the membrane has been the seat of disease before death, and more particularly when the lesion has been of such a kind as to deprive the tissue of its vital properties suddenly. General putrefaction rapidly occurs in many cases of sudden death, especially in those in which the nervous system, or blood, or both, happen to be the vehicles of the destructive agent.

Softening from the action of special secretions may occur in two manners, either by simple maceration, which is long in taking place, or by chemical action. The first may happen in all mucous membranes, the second in the stomach and intestines alone.

Under favourable circumstances, and at a greater or less period after death, we find softening of the coats of the stomach, perforation, and the contents of the viscus free in the cavity of the peritoneum.

Various opinions have been given by the most celebrated pathologists, to account for this phenomenon; some embracing the views of Hunter, and recognising a chemical and post-mortem cause; and others attributing it to certain inflammatory causes, which produced ulceration and subsequent perforation.

Now, Hunter's view is demonstrable by direct experiment, whilst that held by the others is disproved by the absence of symptoms during life sufficient to account for such vast organic changes, and by the difference between such ulceration and those solutions of continuity which we are now about to describe.

The following facts tend to strengthen the first, and militate strongly against the latter opinion. When a rabbit, dog, cat, or any animal, in fact, is killed an hour or so after a meal when digestion is going on, and is allowed to remain in one position and in a moderate temperature, we find, after a few hours have elapsed, that the mucous membrane of the most depending part of the stomach is softened, and can, with the submucous cellular tissue and the muscular coat, be broken down with the greatest facility. The vessels ramifying in the softened part are black from the action of the solvent upon their blood.

After a greater lapse of time we find the peritoneum perforated, and the contents of the stomach in its cavity; by and by the tissues in the immediate neighbourhood of the stomach begin to suffer, and we see the abdominal muscles, and the cuticle covering them, eaten through by the gastric juice.

In fish, softening and perforation occur so rapidly, that, unless perfectly fresh specimens be used, no microscopic structure can be distinguished in the stomachal mucous membrane. I have noticed the same thing to occur in caterpillars: their stomachs, which contain both globular and columnar cells, after a time become softened and are perforated, so, subsequently, is the external cuticle; nature seems to have taken this original method of doing away with useless organisms.

In ulceration of the stomach the affected part is generally circular, and if it reaches the peritoneum excites inflammation in the reflexion contiguous to it; by this means perforation is rarely accomplished. Now, in post mortem perforations the softened part, said by some to be the seat of ulceration, is diffuse and the perforation large and irregular, and no part of the neighbouring peritoneum presents the slightest trace of recent inflammation; shreds of muscular tissue and cellular membrane, moreover, form an irregular fringe around the opening, and, by their presence, detract greatly from the theory which calls such phenomena pathological and not pseudo-morbid.

Generally speaking, the fundus is most frequently the part of the stomach most affected by the gastric juice; but every thing depends upon its being the most depending part, and upon its containing more or less semi-digested food.

The solvent matter is secreted by the tubes of the stomach, and consists of pepsin in combination with lactic acid and water: it possesses the power of disintegrating all dead structures, but cannot influence the living tissues. It is not secreted when the stomach is empty, a stimulus to the mucous coat, in the form of some matter foreign to the stomach, is necessary for its production; it is probably the case, that an ulcer of the mucous membrane may act as a stimulus, and that a certain quantity of juice may always be present in the stomach; and that when, by the depressing effect of this lesion, the general nutrition suffers and the tissues are less able to resist decomposition, the gastric juice may act locally on the surface of the ulcer, and produce perforation before any peritoneal adhesion is formed. Perforation of the coats of the stomach sometimes occurs suddenly after a meal; it is produced generally by the giving way of some small ulcer, the progress of which had been enhanced by the presence of a large quantity of corroding liquid.

Post mortem softening may modify and exaggerate softening from other causes, and differs in its own appearances under various circumstances. The colour which the softened membrane presents appears to depend upon the quantity of blood contained in the organ at the time of death; if the quantity be small and natural, the softened parts are of a dull yellow or orange tint; and this colour increases with the quantity of the blood, and is accompanied by a black colour of the vessels. In infants and young children, and in anæmic patients and persons whose blood is deficient in quantity and altered in quality, containing a great disproportion of serum, the whole stomach appears as if macerated; it is, indeed, sometimes infiltrated with serosity, and is so completely deprived of blood that no trace of this fluid is perceived except in some of the larger veins.

Post mortem softening and perforation of the intestines may occur from the presence of an acid fluid, either within them or without, and derived from the stomach; in the one case, softening is from within outwards, and, in the other, from without inwards.

Softening of the skin: the skin may be softened wholly, or one or more of its layers only. In some skin diseases, especially among scrofulous subjects, there is an alteration of the cohesion of the epidermis, which is properly formed by layers of cells, the row nearest the basement being smallest and more liquid than the others, the more distant being dry and united laterally, so as to form a dense integument. Certain defects in the quantity and quality of the fluid contained in the newest made cells prevent them from progressing, normally, in their development; they do not become dry, neither is any disposition evinced by the basement to secrete other cells; under these circumstances the epidermis is soft, and the basement tender and red, the tissue beneath being visible.

The cutis may lose its consistence in several manners. When considerable quantities of serum are collected in the subcuticular cellular tissue, the cutis becomes mechanically distended and remarkably soft; and sometimes is only represented by a thin friable tissue, which breaks down with the least pressure. It may gradually lose its fibrous structure and degenerate into a tissue analogous to that usually found beneath it.

Softening also occurs as a sequel of acute active local congestion.

The *appendages of the skin*, the nails, hairs, and, in the lower animals, horns, undergo softening to a certain extent in diseases of long standing, attended with great emaciation; and softening of the *cornea* with ulceration is a common symptom of starvation.

Induration of mucous membranes, is generally caused by long continued sub-acute inflammatory action; the sub-basement cellular tissue is generally affected, and thickening of the whole structure, with hypertrophy of the papillæ, where they exist, is found at the same time. Induration with hypertrophy is consequent upon chronic dysentery, and upon chronic inflammation of the bladder. Ulceration of mucous membrane is generally accompanied by surrounding thickening and induration, and this last is frequent in the gall-bladder, gall-ducts, uterus, and urethra. Induration of mucous membranes is generally accompanied by contraction of their caliber or surface, — from the consolidation and subsequent contraction of lymph effused into the cellular structure. Fatal stricture of the intestines is produced in this manner, and so are urethral strictures. Ulceration of the stomach when healed, is followed by contraction of the cicatrix; and when the ulcer has extended into the duodenum from the stomach, pyloric constriction of the severest kind occurs. The colour of indurated mucous membrane is generally paler than natural: the opposite may occur, and the degree of density varies from a slight increase to a bony hardness.

An *indurated* and thickened state of the *membranes of the brain*, *pericardium*, and *pleura*, are found after long continued chronic inflammation, either of the membranes themselves, or of the parenchymatous structures in their vicinity. Effusion of lymph behind serous membranes always tends to their becoming harder and thicker than natural; after a while the lymph becomes organised and contracts, and produces a puckering and irregularity of the membranes. We find thickening and induration of the pleura over large tuberculous cavities, the peritoneum covering the liver, and intestinal canal, and in the sacs of old herniæ. Constriction of any part of the intestinal canal, and also of the pylorus, may be produced by sub-peritoneal effusion of lymph.

Softening of the liver usually occurs in a manner not to be appreciated by the eye, being simply easily broken down under the finger; occasionally, however, the liver looks as if it had been macerated for a great length of time in a dark fluid, its texture has completely lost its cohesion, and has become in certain spots quite diffluent. Livers in a state of softening may retain their ordinary colour, or it may be increased, and even decreased, in an extraordinary manner; for, sometimes, no traces of blood can be found, except in the larger venous trunks, and the tissue of the liver is pale and light drab in colour. Softening of the liver is found frequently on the anterior and convex surface, as a product of inflammation; partial and curable softening has been noticed to accompany inflammation of the right lung; and, finally, the consistence of the liver is much influenced by the abnormal deposition of fat, which sometimes occurs in the ultimate cells of the organ.

Induration of the liver is generally produced by the deposition of lymph, its subsequent contraction and its compressing influence upon the lobules. This effusion is the consequence of adhesive inflammation in the areolar tissue about the twigs of the portal vein, serum and coagulable lymph are poured out, the first is absorbed, and the latter consolidated, and ultimately converted into dense fibrous tissue, which divides the lobular structure of the liver into well defined masses, gives great density and toughness to the organ, by compressing the small twigs of the portal vein, and the small bile ducts, thus impeding the flow of blood and the escape of bile, and causing the usual yellow tint which accompanies this disease.

This deposition of fibrous tissue produces different effects according to the parts it principally involves. Sometimes the lymph is effused exclusively into the cellular tissue of the portal canals of considerable size, and if the person die some time after this has occurred, all the considerable branches of the portal vein are found surrounded, in some places, to the distance of half an inch, by new fibrous tissue, which by its contraction has drawn in and puckered the adjacent portions of the liver. The remaining portions of the liver may be little or not at all altered in texture, and may be readily scraped away from these indurated portions; the main branches of the portal vein are still pervious, but many of the small branches leading from them are obliterated, the parts which they supply atrophied, and the liver correspondingly diminished in bulk. When such portions are near the surface, the capsule is drawn in, thickened and puckered, and generally covered with false membranes.

In other cases, the fibrous tissue is not found around the larger veins, but in the vicinity of the small twigs that separate the lobules; all the substance of the liver is thus rendered tough; and when the organ is sliced, the fibrous tissue is seen to form distinct lines, between small irregular masses of lobules. At the parts on the surface of the liver which correspond to these lines, the capsule is drawn in, so that the organ presents what is termed a hobnailed appearance. The degree of hardness is determined by the amount of the adventitious tissue, and, as a general rule, the denser the organ, the paler its colour; ordinarily, the colour is pale grey, or resembles that of impure wax; and hence the term *Cirrhosis*.

Induration of the liver occurs around growths, abscesses, and hydatid cysts, and may be produced by inflammatory action of a specific or non-specific nature.

Softening of the spleen is produced by an altered state of the fluid which it contains naturally, and by inflammatory action, or by both causes. Softening produced by the first means is common in low fever, intermittents, and scurvy; the fibrous element of the spleen does not suffer; but the blood, which is contained within its meshes, loses its natural consistence, appears to lose its coagulating power, becomes dark, and is washed away, leaving the white fibres intact, by a slight stream of water. In softening from inflammatory action the whole tissue of the spleen is disorganized; it breaks down under the slightest pressure; the external fibrous envelope is much softer than usual; and its internal prolongation is totally destroyed. Both of these kinds of softening occur, with or without alteration, in the bulk and dimensions of the organ.

Induration of the spleen may also arise from an abnormal state of the blood, and from inflammatory action. When the consistence of the blood is altered, the spleen, which may or may not be enlarged, cuts like liver or frozen muscle; and no great quantity of blood follows the incision, the whole tissue being, in fact, denser than usual.

Inflammatory hardening may or may not be equal in degree throughout the whole organ; frequently, certain spots, the seat of old effusions of blood, are denser than the indurated tissue around them; and eccymoses and dark yellow and black spots, are found sometimes scattered over the hardened tissue. This variety of induration may be accompanied by increase or decrease of bulk, or no alteration in size may occur; in degree, it may vary from the slightest increase of consistence, depending upon excessive nutrition, to a bony hardness.

Softening of the kidney is of common occurrence, being frequently found, with an enlarged state of the organ, in several of the diseases comprehended under the term Bright's disease. It exists also in the kidneys of diabetic subjects, and in some cases of renal calculi. When produced by inflammatory action, the softened kidney is dark red, and when a consequence of a perverted state of the nutrition of the organ, it is usually of a pale colour. Generally speaking, the softened state is produced by enlargement of the uriniferous tubes, and a consequent diminution of the solid matrix, or this last only may be affected; and when such is the case, the tissue breaks down with the slightest pressure. In degree, softening may vary from simple flabbiness to a state approaching diffluence.

Induration of the kidney is generally found with an atrophied state of the organ; it is a sequel of acute, and is found in chronic, nephritis, especially in gouty subjects. In these the kidney is frequently indurated, paler than natural, less vascular, and many of its tubes may be blocked up with urate of soda. Induration is sometimes accompanied by an hypertrophied and a darkened state of the organ. In the first stage of induration, the consistence of the organ is slightly exaggerated, and the finger makes no impression on it; in such kidneys we find superficial star-like venous twigs, and more or less confusion of the cortical tissue. In a more advanced stage, the tissue may become nearly as hard as cartilage, and perfectly colourless. Portions only of the kidney may be affected, but, generally, the greater part of it suffers; and it is, comparatively speaking, rare to find cartilaginous induration of one or more of the mammilated processes.

Induration and softening of the uterus are frequently products of acute inflammation of the organ; the first is formed but slowly, the latter with great rapidity, and may or may not be complicated with effusion and infiltration of pus, into the muscular structure. Uncomplicated softening is frequently the result of a more chronic and subacute inflammatory action, and is occasionally found in the impregnated uterus, being made known to the practitioner by the spontaneous rupture of its walls, and the passage of its contents into the cavity of the abdomen. A softening, either general or partial, is found in cases where there were no uterine symptoms during life; the tissue is as friable as that of a softened spleen; but none of the products of inflammation are to be found. It is, probably, produced by a perverted and defective state of the general nutrition; the uterus, from its low vitality, prominently suffering. A putrid sloughy-looking softening occurs around growths and ulcerations of the uterine tissue.

Softening and induration of the ovaries are usually produced by acute or chronic inflammatory action: the one, if found in the early stages of ovaritis, is produced by the effusion of serum into the tissue of the ovary; and the other, a sequel of the same disease, is produced by the contraction and hardening of effused lymph.

In old age, thickening of the fibrous coat, and atrophy, and induration of the stroma, with special hardening around old Graafian vesicles, are very common: this state is frequently preceded by a flabby consistence of the organ.

In the puerperal state, the ovaries are subject to complete softening and disorganization; the natural structure is lost, and, in its place, is a pulpy diffluent bloody-looking mass.

An indurated state of the *prostate gland* is common enough in old age, and is generally accompanied by hypertrophy; and a grey or white hardening of the *testicle* and *epididymis*, with or without destruction of the seminiferous tubes, is frequently found as a sequel of chronic inflammation.

A softened state of the whole or part of the *osseous framework* of the body, is met with in scrofulous habits, and in persons suffering from cancerous cachexia, under the form of rachitis and mollities ossium. In the first of these diseases, there is a deficient deposit of earthy matter, and the animal matter is probably of an unhealthy quality; whilst in the second, the constituents are not deficient in quantity, but bad in quality, and the vital properties of the bone are completely deranged; the osseous structure has lost its cohesive power, and breaks with the least muscular effort. In rachitis, the bones may be bent in any direction, and are easily cut; their centre resembling cartilage. In mollities ossium, the knife penetrates the tissue, which appears to consist of numerous cells, with thin walls, and containing an oleaginous fluid, with the greatest ease. Occasionally, bones are found so softened as to resemble lard in consistence; and sometimes in subjects which have suffered from chronic disease, the ribs are more easily cut through than the cartilages. In caries, also, there is a softening and absorption of the bony texture, which crumbles away on the slightest touch.

Softening of cartilage is found under three forms. It may lose its usual elasticity and become doughy, or the usually dry and elastic cartilage of an adult may be found soft, as if it were that of an infant; it acquires extensibility, and its elasticity diminishes. Finally, the cartilage of adult life may so lose its consistence, as to resemble embryonic cartilage; it becomes pale and transparent, its quantity of solid matter being very small, and its proportion of water great, and the softness considerable.

Fibrous tissue resembles cartilage in its alterations of cohesion, and both are apt to become indurated by a deposit of osseous matter.

Softening of the muscular structures may occur, as a sequel of inflammation in the cellular tissue which surrounds and binds together the ultimate fibres; or as a result of long continued inaction, produced by loss of nervous influence, as in paralysis, or by long standing disease. Softened muscles are pale, flabby, and contain much fat; are incapable of long or severe action, and are deficient in irritability.

Softening of the muscles of organic life, generally depends upon an inflammatory condition of their neighbouring submucous or subserous cellular tissue.

Softening of cellular tissue is very common. It has already been noticed as occurring from effusion of serum, pus, and blood. These render it more palpable and more liable to be torn, and its simple lacerability is frequently set down to softening: it is difficult, however, to draw the line. A great consequence of softening of the cellular tissue, is softening of the subjacent and neighbouring tissues; we have noticed this to a considerable extent in softening of the sub-pleural tissue, and also of the submucous and subperitoneal tissue of the alimentary canal.

There is hardly any part of the body in which cellular tissue is not to be found; and consequently nearly all the tissues may be influenced by its softened state. The effusion of fluids into the areolæ of the cellular tissue, may follow inflammatory action or may be produced from a malignant or typhoid state of system, and from post mortem causes.

The colour of the softened membrane depends upon the nature of the effused fluid.

Induration of cellular tissue is generally caused by the effusion, and subsequent contraction and hardening of coagulable lymph; or the simple effusion may produce hardening, as in the immediate vicinity of old ulcers. However, it is notorious that even in this case contraction and consolidation occur at a little distance from the seat of irritation; in certain skin diseases, and in the cicatrices following burns, great injury may be effected by the contracting power of the effused lymph.

But it is behind mucous and serous, or serofibrous membranes, that induration from inflammatory action principally occurs, and leads to effects, most noxious to the general economy; strictures of the gullet, pylorus, intestines, and urethra, depend upon the submucous or subserous effusion and consolidation of lymph.

A hardened state of the mammary gland depends upon the same cause. Dense, crisp-cutting consolidations of cellular tissue, are frequently mistaken for scirrhus, and, indeed, are frequently the seat of morbid growths.

Induration of the cellular tissue may depend upon a perverted state of the general nutrition; in syphilis, for example, there is frequently subperiosteal effusion of lymph, which has a tendency to ossify. It is also very frequently brought about, and becomes cartilaginous in hardness, by long continued local irritation. We notice the indurated state of the tissue around scrofulous glands, and its condensed form around miliary tubercles. The disease, which has been termed hardening of the cellular tissue, occurs in infants. The subjects of this disease are, for the most part, feeble, sometimes imperfectly developed, and generally born before the full period. It is a disease seen, for the most part, in hospitals, and is found where filth, bad ventilation, and worse food abound; consisting, in a wax-like hardness of the subcutaneous cellular tissue, and is produced by the effusion of a sero-albuminous fluid into its meshes. This effusion produces swelling of the affected parts, as well as hardening; and occurs, first of all, in the inferior extremities, passes from the feet upwards, and subsequently attacks the hands, arms, and then the trunk itself.

The hardened limbs are dry, cold, and may or may not pit on pressure; their colour is either unchanged, or has a dull yellow or a lived hue. Symptoms of obstructed respiration supervene before death.

When a section of an affected limb is made, and the subcutaneous cellular tissue is well exposed, we find its cellular appearance much increased, from the interstices being filled with a fluid, which is either limpid, or more concrete, and of a citron colour, or tinged with blood. The quantity of this fluid determines the degree and amount of induration; and occasionally the fatty structure beneath the skin is hardened from the compressing influence of the effusion.

It is very doubtful if the effused fluid becomes wholly concrete. Chevreul says, that the serum of the blood, in infants affected with hardening of the subcutaneous cellular tissue, contains a large quantity of a spontaneously coagulable matter, analogous to that which is effused into the affected tissue. Great and general venous congestion is always found in these cases, and would seem to depend on insufficient vital energy, produced by the depressing influences of damp, bad nourishment, and cold.

For some particulars respecting the Softening and Induration of " Growths," see article on Adventitious Products.

(*P. Martin Duncan.*)

SOLIPEDA. Syn. *Solidungula, Pachydermes Solipedes.* — An important group of herbivorous quadrupeds, regarded by Cuvier as constituting a third family of his order Pachydermata, and defined as " animaux à sabots non ruminans," or non-ruminant, ungulate quadrupeds. They form, however, a race of animals that presents many remarkable peculiarities of structure, and, from their great importance to mankind, demand, in a work like the present, a somewhat minute description of their anatomy and general organisation.

The Solipeda, zoologically considered, comprehend but the single genus EQUUS, at once distinguishable from all other quadrupeds by the remarkable construction of the anterior and posterior extremities, each of the four feet appearing externally to consist of but a single toe enclosed in a solid hoof of horn, although, within, there are found concealed beneath the skin the rudiments of two other digits, appended to each side of the metacarpal and metatarsal portion of the limb.

The genus EQUUS is further characterised by the following peculiar disposition of the dental apparatus: — There are six sharp and trenchant incisors both in the upper and in the lower jaw, and an equal number of grinding teeth, the crowns of which are of a square form, each having its surface intersected by deep plates of enamel, arranged in the shape of four crescentic masses, in addition to which there exists in the teeth of the upper jaw a small disc of enamel, situated upon the inner border of each tooth.

The males have, moreover, two small canine teeth developed in the upper jaw, and sometimes in the lower one also; but these canine teeth, or *tushes* (tusks), as they are generally called, are for the most part altogether wanting in the females. A considerable interspace exists between the canine teeth and the first molar, so that that portion of the mouth of the horse which is opposite to the commissure of the lips is devoid of any dental armature, a circumstance of which man has availed himself for the purpose of introducing into the mouth of these animals that bit by the aid of which he is enabled to subjugate his steed, and thus secure to himself the services of an assistant not less conspicuous for his indomitable strength than for his matchless docility. The stomach of the Solipeds is simple in its form, and of moderate dimensions, but their intestinal canal is of very great length, and the cœcum and colon enormous in their proportionate size.

Thus characterised, the genus Equus is found to comprehend several different races of quadrupeds that are generally regarded by modern naturalists as constituting so many distinct species. These are — 1st. The Horse (*Equus Caballus*), "man's noble companion in the chase or on the battle-field, in the labours of agriculture, in the arts, or in commerce." The original country whence the horse has been disseminated through the whole world has now become a matter of uncertainty, although most probably the wide plains of eastern Europe and of Asia, where wild horses still abound, may be pointed out as their central station. That they were in common use in Egypt from the very earliest period of which we have any record, is evident from the sacred writings (*vide* Gen. c. xlvii. v. 17., and c. l. v. 9.), and hence it is supposed to have been derived by the Arabs, Persians, Ethiopians, Indians, Parthians, Scythians, &c. At the present day, wild horses are by no means common even in their native regions, owing to the encroachments of man upon their original haunts; but, on the other hand, they have spread over the vast prairies of the new continent, and may now be said to be as extensively distributed as the human race itself.

The second species admitted by zoologists to form a distinct race is the Dzigguetai (*Equus Hemionus*), intermediate in size between the horse and the ass, from both of which it is distinguished by its colour, which is light bay, with a black mane and dorsal line, and it also has a black tuft of hair at the end of its tail. This animal is found in large troops among the sandy plains of Central Asia.

3d. The ass (*Equus Asinus*), at once recognisable by the length of its ears, by the tuft of hair at the end of its tail, and by the black cross upon its shoulders, which is the first appearance of those transverse bands which become numerous in the succeeding species. This animal seems to be indigenous to the desert regions of Central Asia, where vast troops of them still abound in a wild state.

4th. The Zebra (*Equus Zebra*), a native of the southern regions of Africa, and conspicuous for its symmetry and the alternate transverse stripes of black and white with which its skin is all over marked.

5th. The Quagga (*Equus Quaccha*), a native of the same regions as the Zebra, from which it principally differs in the colour of its skin and more horse-like appearance. Its hair upon the neck and shoulders is brown, marked transversely with white stripes; its croup is of a greyish-red colour, while the tail and legs are white. The name of this animal is derived from its peculiar voice, which somewhat resembles the bark of a dog.

6th, The Onagga, or Dauw (*Equus montanus*), is somewhat less than the ass, and in its shape resembles the quagga. Its general colour is a light bay marked with black stripes, that are alternately broader and narrower over the head, neck, and trunk; the hinder stripes are directed obliquely forward, while the legs and tail remain white.

With respect to their anatomy, it may be observed, that all the above species resemble each other as closely in their internal economy as they do in outward form, and accordingly, in the following pages, we shall confine ourselves principally to a description of the horse, as being the typical species of the group, noticing, however, incidentally, such peculiarities of structure as may be worthy of remark in the humbler congeners of their noble prototype. So near, indeed, is the relationship between the different members of the entire genus, that they will breed together without difficulty, although the progeny of such a union, the mule, is generally incapable of reproduction. Such is well known to be the case between the horse and the ass, as also with the zebra, and doubtless with the genus generally.

Osteology.—*Skull.* The head of the horse is at once recognisable by the following characters*, namely, by the great enlargement between the orbits (*fig.* 496. *a a*), by its slightly

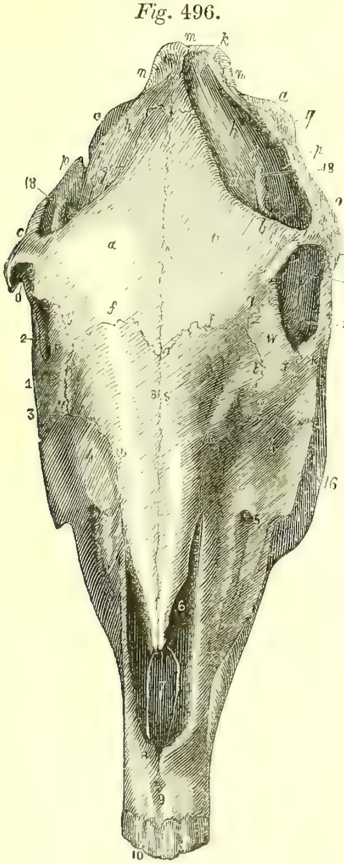
a, b, c, d, e, f, os frontis; *b,* supra-orbital foramen; — *h, i, k,* parietal bone; — *l, o, p, q,* occipital bone; *l,* occipital protuberance; *p,* condyle; *o,* paramastoid process; *q,* basilar portion;—*r, s, t, u, w, x,* temporal bone; *r,* zygomatic portion; *x,* suture with the malar bone; *t,* glenoid cavity; *u,* mastoid process; *w,* tympanic ring;—1, 2, 3, 4, 5, 6, lacrymal bone; 2, position of the nasal duct; — 7, 8, 10, malar bone; — 11, 11, 12, 13, 14, superior maxillary; 12, infra-orbital foramen;—15, intermaxillary;—16, nasal bone; — 17, 18, 19, 19, 20, inferior maxillary; 18, mental foramen; 19, 19, coronoid process; 20, condyle.

Fig. 496.



A, a, a, b, c, c, d, d, f, f, g, g, frontal bones; *A,* frontal suture;—*h, h, i, i, k,* parietal bones; — *m, n, n,* occipital; — *o, o, o, p, q, r,* temporal bones; *o, o, o,* zygomatic processes; *r,* suture with the malar; — *s, s, t, u, u,* nasal bones;—*w, x, y, z,* lacrymal bone;— 1, 1, 2, 2, 3, 3, malar bones; — 4, 4, 5, 5, 6, superior maxillary bones; 5, 5, infra-orbital foramina; 6, palatal process; — 7, 8, 9, intermaxillary bones; 8, nasal process; 7, palatal suture; 9, foramen in the suture; 10, incisor teeth;—16, 18, 18, inferior maxilla; 18, 18, summits of coronoid processes.

convex profile, by the length of the face, which is more than double that of the cranium, and by the vertical depth of the lower jaw, which is more than that of the whole cranial portion of the skull. The temporal ridges, prolonged backwards from the post orbital apophyses, extend as far as the middle of the parietal bones, and there form a short sagittal crest upon the mesial line of the skull, whence, proceeding backwards, they diverge and extend as far as the occipital ridge, which is truncated above (as is the case in the pachydermata generally), and projects over the posterior surface of the occiput. The intermaxillaries are prolonged considerably beyond the nasal bones, which last, by their points, arch over the cavity of the nostrils to a considerable extent. The temporal arch is comparatively very short, nearly straight, and is situated entirely in the posterior third of the skull.

As regards the individual bones of the skull, it may be observed that the two *frontals* (*fig.* 496. *a, a, f, g*) remain distinct from each other after the parietals become consolidated into one piece; they are of remarkable breadth between the orbits, and posteriorly penetrate to a considerable depth between the parietal bones. The *ossa parietalia* (*fig.* 495. *h, i*) give off on each side of the cranium a pointed

* Cuvier, Ossemens fossiles, t. ii. p. 108.

process, which encroaches largely upon the squamous process of the temporal bone. The zygomatic process of the temporal (*fig.* 496. *o*) has at its base a process which projects upwards and backwards. This process constitutes the entire length of the temporal arch, articulating anteriorly by suture with the post-orbital process of the os frontis (*fig.* 495. *b, c*), which is very long: the zygomatic process of the temporal even extends to beneath the orbit, the bony circle around which it contributes to form, and is thence prolonged behind the *os malæ*, so as to become articulated with the superior maxillary bone. The occipital suture is situated considerably in front of the superior occipital ridge; nevertheless there is generally an interparietal bone of quadrangular shape, called by hippotomists the *os quadratum*, but which at an early age becomes consolidated with the two parietals. The interparietal is, indeed, itself frequently divided into two pieces in the new-born foal. It is always much too narrow to reach as far as the temporals.

The anterior sphenoid appears but very slightly in the orbit. The posterior sphenoid mounts upwards in that region almost as high as the temporal, but without coming in contact with the parietal. Inferiorly, it is prolonged in a square form considerably beyond the pterygoid region. The glenoid cavity for the articulation of the lower jaw is situated beneath the middle of the temporal arch; it is convex inferiorly, and has a tubercle situated behind its internal extremity, behind which, and on the same level, is situated the *meatus auditorius externus*. The bony meatus remains distinct from the temporal even when it has become completely consolidated with the tympanic and petrous portions of that bone. The tympanum is but little prominent, and of a very irregular shape. The petrous portion appears externally at the side of the occiput (*fig.* 495. *u*), in front of the base of the para-mastoid apophysis (*fig.* 495.*p*),which is here long and pointed.

Of the bones of the face it may be observed, that the ascending apophyses of the intermaxillary bones (*fig.* 495. 15) are placed very obliquely, and become connected with the ossa nasi at about one third of the length of those bones from their anterior extremity. Inferiorly, their palatine apophyses penetrate between the maxillary bones as far as the first molar teeth, leaving two incisive foramina, or rather fissures, which are about half the length of the apophyses themselves. The pointed extremities of the ossa nasi arch over the cavity of the nose nearly as far as the middle of the intermaxillary bones. Superiorly, the ossa nasi increase in breadth as far as the inner angles of the orbits, where they become joined with the lacrymals (3, 4, 5, 6), which descend to a considerable distance upon the cheek, and enter almost as largely into the structure of the orbital cavity. The *jugal* (*fig.* 495. 7, 8) advances upon the cheek as far forwards as the lacrymal bone, and terminates beneath the middle of the orbit. This bone does not extend sufficiently far backwards to enter into the composition of the zygomatic arch, properly so called. It forms upon the side of the cheek, by its union with the maxillary bone, a broad, square ridge, which is continued backward as far as the commencement of the zygomatic arch.

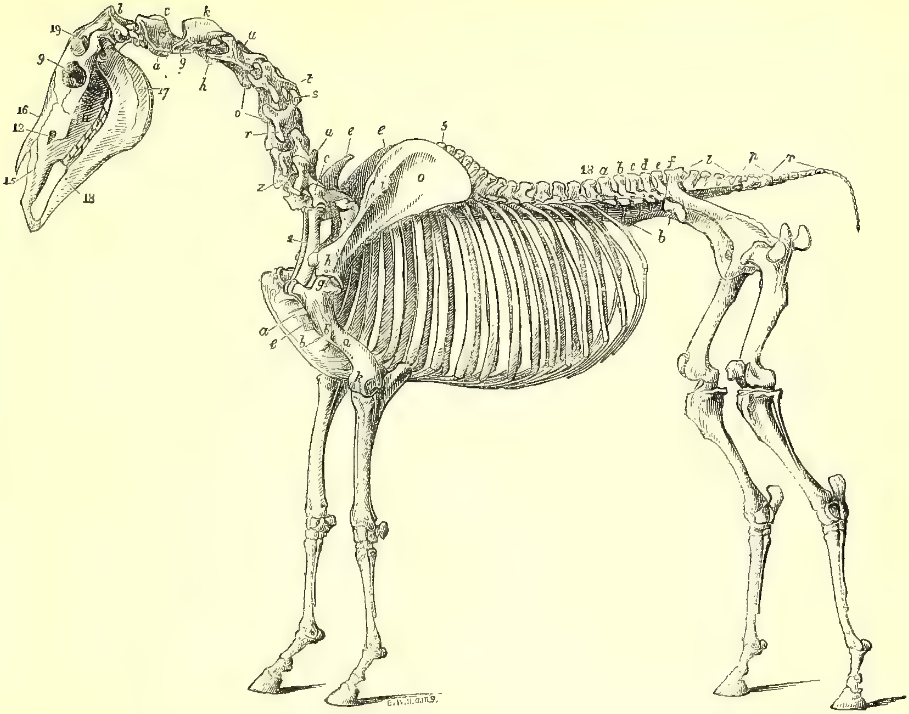
The palatine bone is deeply notched and very narrow, not extending forward beyond the penultimate molar tooth. This bone merely forms a narrow border around the meso-pterygoid fossa, but it composes more than two thirds of the pterygoid alæ. In the floor of the orbit it mounts upwards, between the maxillary bone on one side, and the two sphenoids on the other, as far as the os frontis, but it does not come in contact with the lachrymal. The external pterygoid process of the sphenoid runs along the palatine externally, and extends beyond it, but the internal pterygoid process is distinct from the sphenoid, forming a long and narrow tongue-like process, which, after having covered the lateral suture of the anterior end of the posterior sphenoid, extends obliquely over the centre of the pterygoid process of the palatine, and proceeds to form a bony hook, situated upon the side of the great palatine fissure.

Spinal column.—The *cervical vertebræ* of the horse are, as in all mammiferous quadrupeds, seven in number; their proportions are massive, and the whole series forms a chain of great strength and considerable flexibility. All the posterior vertebræ of the neck have in the horse a square or oblong shape, and both the spinous and transverse processes are short and stunted, so as not to interfere with that freedom and extent of motion which is essential in this portion of the spine.

The *atlas*, as in man and other mammifera, presents characters peculiar to itself. The body of this bone is entirely suppressed, its place being supplied by the two articulating surfaces appropriated to the reception of the condyles of the occipital: the superior lamina are broad and flat, and the superior spinous apophysis is not developed; whilst, instead of transverse processes, the vertebra is prolonged laterally into two broad alæ, into which numerous muscles are implanted. In the horse it may be remarked that the entrance of the canals for the passage of the vertebral arteries, instead of being situated at the posterior edge of the transverse apophyses, is placed upon its upper surface, but in other respects this bone presents no peculiarity worthy of special notice.

Axis. — The configuration of the second cervical vertebra in most quadrupeds differs considerably from what is met with in the human subject, owing to the horizontal direction of the neck, and the unfavourable position in which the head has to be sustained. This difference is most remarkable in the arrangement of the spinous process, which, instead of being merely a prominent tubercle, as in man, is prolonged into a vertical crest that

Fig. 497.



Skeleton of the Horse. (*After Stubbs.*)

Skull.—9, orbit ; 11, 12, superior maxillary bone ; 12, infra-orbital foramen; 15, intermaxillary; 16, os nasi; 17, 18, 19, lower jaw; 18, mental foramen; 19, coronoid process. *Cervical region.* — *a*, *c*, the atlas; *g*, *h*, *k*, the vertebra dentata; *o*, body; *r*, transverse; *s*, *t*, oblique, and *u*, spinous processes of cervical vertebræ ; *z*, process from the root of the transverse process of the sixth cervical vertebræ, assisting with its fellow to form the groove in which the longus colli muscle is lodged. *Dorsal region.*—*c*, oblique, and *e*, *e*, spinous processes of the two anterior dorsal vertebræ; 5 to 18, continuation of dorsal spinous processes. *Lumbar region.*—*a*, *b*, *c*, *d*, *e*, *f*, lumbar vertebræ; *l*, the sacrum; *p*, superior, and *r*, inferior, caudal vertebræ. *Sternal region.*—*a*, *b*, *c*, osseous and cartilaginous pieces of the sternum with the cartilaginous attachments of the true ribs. *Shoulder.*— *h*, *i*, *o*, the scapula; *b*, *g*, *k*, the os humeri.

sometimes advances forwards above the atlas and is prolonged posteriorly above the third, or even the fourth, cervical vertebra, thus affording an ample expansion for muscular attachments. In the Solipeds, this spinous crest (*k*) is but moderately developed, extending backwards so as to overlap the third vertebra to some extent ; but its anterior prolongation is wanting. The transverse apophyses are short, and perforated by the vertebral canal, while the articular processes are but moderately developed, and directed backwards to articulate with those of the succeeding vertebra.

The five posterior cervical vertebræ are remarkable for their strength and mobility ; their bodies are of great proportionate size, and articulated together by broad sub-globular surfaces that allow a considerable extent of motion ; the vertebral laminæ are broad and massive, and the articular processes well developed and connected together by large articulating surfaces. The spinous processes are almost wanting except upon the sixth and seventh vertebræ, that belonging to the latter being of considerable size and turned backwards, so as to represent the commencement of the dorsal series of spines. The bodies of the sixth and seventh vertebræ of the neck, more particularly of the former, are prolonged inferiorly into a central crest of considerable size, which projects downwards and backwards, and gives origin to the *longus colli*, which muscle is likewise lodged in a kind of groove formed by osseous plates derived from the transverse processes.

The *dorsal vertebræ* in the Solipeds are invariably eighteen in number, and are distinguished by the shortness of their transverse apophyses, each of which is provided with an articulating surface, whereby it is connected with the corresponding rib as well as by similar articulations situated on each side upon the anterior and posterior extremities of their bodies to which the heads of the ribs are affixed. The spinous processes of the anterior dorsal vertebræ are of great length, and dilated at their extremities, where they give origin to the broad elastic cervical ligament by means of which the weight of the head is in a very material degree supported; posteriorly, the spinous processes of the dorsal region become gradually shorter, and their extremities broad and flattened, so as gradually to approximate in their shape those of the lumbar region.

The *vertebræ of the loins* are, in the Solipeda, usually six in number: such is the case in the horse, zebra, and quagga; but in the ass there are but five lumbar vertebræ. This portion of the vertebral column is, in the class under consideration, possessed of great strength; the bodies of the vertebræ are broad and firmly bound together; the transverse processes of remarkable length and power; the articulating apophyses strong and broadly connected with each other, while the spinous processes, which are of great breadth, are either quite straight or inclined forward.

The *sacrum* in all the Solipeda is composed of five vertebræ consolidated into one piece, and, with that exception, scarcely different from the vertebral pieces that immediately precede and follow it. In the horse, as in most quadrupeds, the sacrum is much narrower in proportion than in the human subject, and forming, moreover, a continuous straight line with the rest of the spinal column, allows of much more freedom of motion in this part of the skeleton than is possible in the human subject; and this is much increased by the obliquity of the junction between the sacrum and the iliac bones. The articulation, moreover, between the last lumbar vertebra and the sacrum, still further adds to the mobility of these parts; for in the horse, the oblique processes of that vertebra are connected with the sacrum by means of articulating surfaces of very large size, so that from the combination of all these circumstances, there is a springiness given to this region of the vertebral column, the importance of which, in galloping or leaping, is at once conspicuous.

The *caudal vertebræ* in the solipeds vary in number from seventeen to twenty-one; but of these, the upper ones only resemble true vertebræ. Even in the first caudal vertebra, the inferior oblique processes become obliterated, and as we descend, all the vertebral apophyses rapidly disappear: at the second bone of the tail, the spinal laminæ no longer rise high enough to enclose the spinal canal; but resemble two short processes; and at about the fifth or sixth, all vestiges of them are lost, nothing remaining but the bodies of the vertebræ of a cylindrical shape and slightly enlarged at each extremity, until we approach the last, where all regularity of form is lost.

Thorax. — The *sternum* of the solipeds is considerably compressed towards its anterior extremity, which is moreover prolonged to some extent beyond the insertion of the first rib, so as to give to the whole chest a carinated appearance, which forcibly reminds the anatomist of the thorax of a bird. Posteriorly, the carinated form disappears, and the sternum becomes broad and flattened where it receives the cartilages of the posterior true ribs. The sternum of the horse is composed of several osseous pieces bound together by strong ligamentous and cartilaginous connections.

The *ribs* are eighteen in number, so that the thorax is prolonged very far backwards towards the pelvis. The anterior ribs are broad and massive; but of these, eight only are attached to the sternum: the posterior or false ribs gradually become more slender as they recede backwards to expand over the cavity of the abdomen.

Anterior extremity.—The frame-work of the shoulder in the Solipeda, as in all ungulate quadrupeds, is composed of the scapula only; the coracoid apparatus being dubiously represented by a rudimentary apophysis, and the clavicle is totally wanting in circumstances which allow of the close approximation of the shoulder blades to the sides of the chest, and thus cause the weight of the body to be transmitted perpendicularly to the ground.

The shape of the *scapula* (*fig.* 498. *o*) is almost that of an isosceles triangle, the spinal costa, which is about half the length of the other two, having its angles rounded off. The spine of the scapula is prominently developed, and towards its upper third, projects posteriorly, so as to form a considerable recurved process (*i*); as it approaches the neck of the bone, however, the scapular spine becomes quite obliterated, spreading out upon the margin of the glenoid cavity (*h*), so that no acromion process exists in these quadrupeds.

The *humerus* (*fig.* 498. *e, b, k*) is short, but of great strength, and the muscular imprints strongly marked.

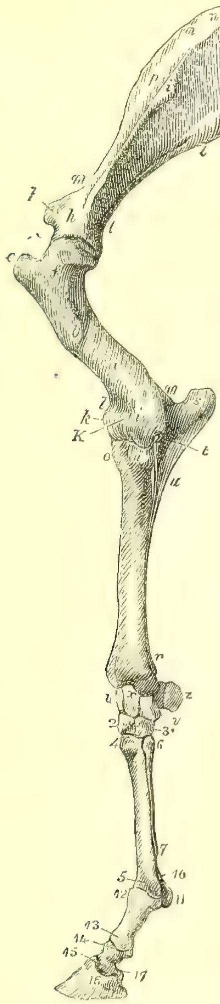
The *forearm* is almost exclusively formed by the *radius* (*fig.* 498. *o, r*), the strength of which is in accordance with the enormous weight it has to sustain, while the *ulna* is reduced to a mere appendage (*fig.* 498. *s, t, u*), which in the adult animal is completely consolidated with its posterior surface, the line of demarcation between the two being only indicated by a furrow which, towards the upper extremity of the forearm, deepens into a slight fissure. The olecranon process is, however, of large size, and, by its projection posteriorly, affords a powerful purchase to the massive extensor muscles inserted into this portion of the limb. From the above arrangement of the bones of the forearm, it is manifest that all movements of pronation and supination are here out of the question; the limb must remain constantly fixed in a state of pronation, in which condition it is anchylosed, and thus acquires a firmness and steadiness which would be quite incompatible with more extensive movements.

The *carpus* in the Solipeda consists of seven bones arranged in two rows, — of which four are situated in the first, and three in the second.

The upper series consists of the representative of the *os scaphoides* of the human subject (*fig.* 498. *w*); of the *os lunare* (*x*); of the *cuneiforme* (*y*); and of the *os pisiforme* (*z*).

In the lower series, the *os trapezium*, which supports the thumb of the human hand, does not exist in the horse; but the *trapezoid* (not seen in the figure); the *os magnum* (2.); and the *unciforme* (3.) are all of them readily identified.

Fig. 498.



Osteology of the Horse — Bones of the anterior Extremity.

Scapula.— *h*, its neck; *i*, spine; *k*, coracoid apophysis; *l*, *l*, inferior costa; *m*, *m*, superior costa; *n*, *n*, base; *o*, fossa subspinalis; *p*, fossa supra-spinalis.

Os humeri. — *a*, shaft of the bone; *b*, protuberance into which the teres major is inserted; *e*, bicipital protuberance; *f*, neck of the humerus; *i*, external condyle; *K*, double articular suface, articulated with the radius; *k*, internal condyle; *l*, anterior fossa which receives the upper head of the radius, when the fore-arm is bent; *m*, posterior sinus, for the reception of the olecranon of the ulna, when the fore-arm is extended.

Radius. — *n*, its upper head; *o*, protuberance for the insertion of the tendon of the biceps; *r*, its lower extremity.

Ulna.— *s*, the olecranon process; *t*, its articulation with the humerus; *u*, continuation of the bone which in aged horses becomes united with the radius.

Bones of the carpus.— *w*, Scaphoides; *x*, Lunare; *y*, Cuneiforme; *z*, Pisiforme or Orbiculare; 2, Os magnum; 3, Unciforme.

Metacarpus.— 4, 5. The great metacarpal or cannon bone. 6, 7. Rudimentary external metacarpal bone. 10, 11. Sesamoid bones.

Fore-foot. 12, 13. Proximal phalanx or great pastern bone. 14, 15. Middle phalanx or lesser pastern or coronary bone. 16. Terminal phalanx or coffin-bone. 17. Sesamoid bone.

The *metacarpal bones* are in the horse consolidated into one large piece, called by farriers the shank or cannon bone, and two smaller supplementary pieces, which seem merely appendages to the former.

The large cannon bone (*fig.* 498. 4, 5.) is formed by the union of two metacarpal bones indissolubly conjoined, — viz. of those which support the ring and middle fingers in the human hand; these conjoined, here form a massive piece, the upper end of which articulates with the carpus, while its distal extremity sustains the first joint of the foot.

A second or supplemental piece (*fig.*498.6,7.) is simply a rudiment representing the internal metacarpal bone of the human skeleton, or that which in man supports the little finger; superiorly this piece presents an articulating surface, which articulates with the unciform bone of the carpus, but inferiorly, there being no finger for it to support, it gradually dwindles away to a mere splint, which is applied against the ulnar aspect of the preceding bone.

The third bone of the metacarpus is equally rudimentary as the last, and consists of a similar styliform bone applied against the opposite side of the shank bone, and obviously representing the metacarpal bone of the fore finger.

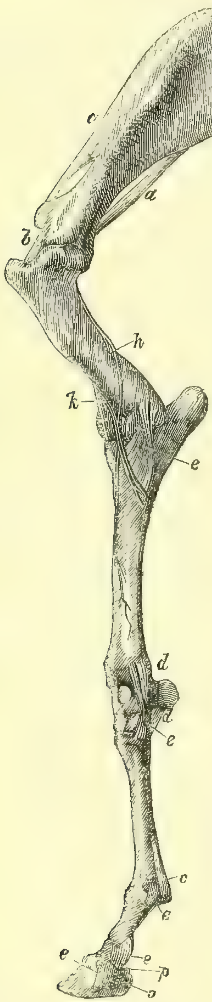
The fore foot of the horse is composed of three bones, representing the first, second, and third *phalanges* in the fingers of the human hand; but extraordinarily changed in their appearance. Of these, the first (*fig.* 498. 12, 13) is equivalent to the bones of the first phalanges of the ring and middle fingers in the human subject, as is indicated by a central groove, showing this piece to be composed of two lateral halves — this bone in the horse is called the "*great pastern.*"

The second piece (*fig.* 498. 14, 15.) corresponding with the second phalanx, is named, in common language the "*little pastern,*" while the third (16), the representative of the third phalanx, a bone of very large size and crescentic shape, has received from farriers the name of the "*coffin bone.*"

In addition to the above may be noticed two *sesamoid bones* (10, 11) implanted in the flexor tendon of the foot, as it passes behind the articulation between the cannon bone and the great pastern, and a third lying over the posterior part of the articulation, between the coffin bone with the coronary bone, or between the two distal phalanges.

Posterior extremity. — The *pelvis* of the solipeds, both in its disposition and in the shape of the bones composing it, differs in many important particulars from that of man, and even of the generality of quadrupeds. The body of the ileum is elongated into a sort of neck, while its crest and spine, extending themselves outwards almost at a right angle with the body, give the whole bone a shape somewhat like that of the letter T, or of a hammer, of which the body of the bone will form the handle, while the extremity of one of its branches is articulated to the side of the sacrum, and the other forms a broad expansion, the inner surface of which is turned obliquely towards the spinal column. The body of the ileum joins the ischium and pubis at a very obtuse angle, the cotyloid cavity being excavated in the usual manner in the line of junction between the three bones.

Fig. 499.

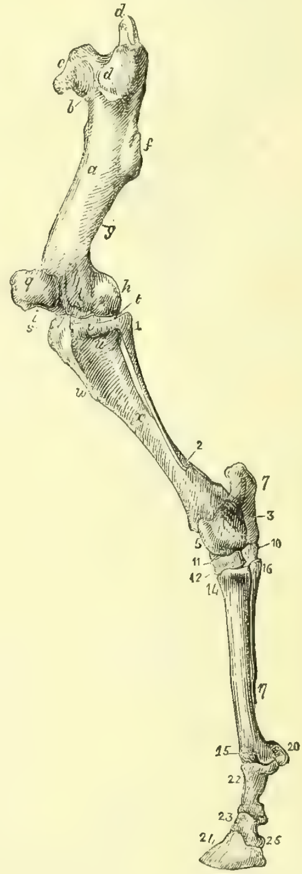


Ligaments of the anterior extremity of the Horse.

a, a, Ligaments of the scapula; *b,* capsular ligament of the shoulder-joint; *h,* radial nerve; *k,* capsule of elbow-joint; *d, d, d, e, e, e,* ligaments of the elbow, carpus, and phalanges; *o,* outer cartilage of the hoof; *p,* inner cartilage of the hoof.

The *os femoris* in the Solipeda is very strong and massive, with well developed trochanters, and prominent ridges for the attachment of the muscles implanted into it: it is however so short as to be entirely concealed within the flesh and integuments of the trunk, so that what is ordinarily designated the thigh in these quadrupeds is in reality the muscular portion of the leg. Inferiorly the articulating surface that sustains the patella is no longer, as in the human subject, continuous with that of the knee-joint, but forms a distinct articulation upon which the patella (*fig.*500. *q*) plays during the movements of the leg.

Fig. 500.



Osteology of the Horse.— Bones of the posterior Extremity.

Femur.— a, Body of the bone; *b,* its neck; *c,* the head incrusted with cartilage; *d, d,* trochanter major, or "spoke"; *f,* projection of the linea aspera, into which the glutæus externus is inserted; *g,* fossa, whence arises the gastrocnemius externus and plantaris; *h,* the external condyle; *i,* cartilaginous surface supporting — *q,* the patella.

s, t, external and internal semilunar cartilages of the knee-joint.

Tibia.— u, its upper head; *v,* articular surface, entering into the composition of the knee-joint; *w,* surface for the insertion of the ligamentum patellæ; *x,* shaft of the bone.

Fibula. — 1, Its upper extremity; 2, its lower end gradually diminished to a point.

Tarsus.— 3, 5, Astragalus or cockal bones; 7, os Calcis; 10, os Cuboides; 11, os Naviculare; 12, os Cuneiforme.

Metatarsus.— 14, Upper extremity, and 15, lower extremity of the great metatarsal or cannon bone. 16, 17, rudimentary external metatarsal bone; 20, Sesamoid bone.

Hind-foot.—22. Proximal phalanx, or great pastern; 23. Middle phalanx, or lesser pastern, or coronary bone; 24, Last phalanx or coffin bone; 25, Sesamoid bone.

The *leg* is in the Solipeda almost exclusively formed by the *tibia*, which is of great strength, and very massive towards its upper extremity, where the ridges for muscular attachment stand out in bold relief; inferiorly it becomes more slender, and approaches nearer to a cylindrical shape, expanding again inferiorly to form the articulating surface for the ankle joint.

The *fibula* (*fig.* 500. 1, 2.) is even more rudimentary in its development than the ulna in the anterior extremity, being, in fact, nothing more than a long spiculum of bone implanted among the muscles, and laid like a slender splint along the outer and posterior angle of the tibia, with which it is firmly connected by ligamentous attachments in the vicinity of the knee-joint, whence it descends separated by a small interval from the tibia as far as the middle of that bone, to which at this point it becomes closely applied, and then, gradually becoming more and more attenuated, is towards the lower third of the leg completely lost.

The bones of the *tarsus* in the horse are, 1st, the astragalus, or "cockal-bone," as it is vulgarly named (*fig.* 500. 3, 5.), the os calcis, or "heel-bone" (7), the cuboid (10), the navicular (11), the middle cuneiform and the lesser cuneiform (12). The internal or great cuneiform bone is here wanting, as also are the bones of the great toe, which, when present, it is destined to support.

The bones of the *metatarsus*, like those of the metacarpus, are three in number,—viz. one large central or cannon bone, and two lateral rudimentary pieces. The central piece (*fig.* 500. 14, 15.), which supports the entire weight of the body, is apparently composed of the conjoined metatarsal bones belonging to the second and third smaller toes; in the human skeleton the line of demarcation between the two being indicated by a deep longitudinal groove: by its upper extremity this bone articulates with the three lower bones of the tarsus; while inferiorly it presents a smooth articular surface, whereby it supports the first phalanx of the foot. The external rudiment (*fig.* 500. 16, 17.) is an imperfect metatarsal bone, occupying the place of that which in the human subject supports the little toe: by its upper extremity it articulates with the cuboid bone of the tarsus, while inferiorly, owing to the deficiency of the corresponding toe, it forms no articulation. The internal rudiment represents the metatarsal bone of the first of the small toes in the human foot: superiorly it articulates with the lesser cuneiform bone of the tarsus (12), whence, as it descends, it gradually diminishes in size, and is lost before it reaches the foot.

The bones of the hind foot resemble those already described in the anterior extremity, and are distinguished by similar names, the first *phalanx* of the solitary toe being the great pastern, the second the little pastern or coronary bone, and the third, or that which supports the hoof, the coffin bone: there are likewise the *sesamoid bones* (20), behind the articulation, between the cannon bone and the first phalanx, and also between the coronary and coffin bones (25).

Myology. — The myology of quadrupeds is, in many points of view, a subject of particular interest, more especially in those races which are far removed from man in their general habits or in the configuration of their skeleton. In the case of the Solipeds, owing to the exceedingly aberrant structure of their extremities, the disposition of their muscular system becomes a very important subject of inquiry, and it is partly from this cause, and partly from the necessity of obtaining an accurate knowledge of the anatomy of animals so valuable to mankind, that the myology of the horse and its congeners has been studied with great care, and delineated with extraordinary zeal and perseverance. It is for these reasons that we shall in the present article describe at some length this portion of their economy, premising that the details here given will be found more or less applicable to quadrupeds generally, except where obvious peculiarities of structure belong to the class which forms the more immediate subject of our study.

Panniculus carnosus. — On removing the skin, the entire body is in most quadrupeds found to be invested with a muscular covering, the thickness and consequent importance of which varies in different parts. In the human subject the traces of this fleshy pannicle are very feeble, being confined to certain regions,—such as the anterior part of the neck, the palms of the hands, &c.; but in the horse it forms a much more important investment, giving mobility to the integument, and materially contributing to the support and defence of various organs. This fleshy covering is very thick in the anterior region of the neck, whence it extends downwards upon the anterior extremities, and, becoming tendinous, is extensively inserted in conjunction with the tendons of the latissimus dorsi and teres major, into the external surface of the humerus. From this point strong muscular fibres pass downwards over the muscles of the fore-arm, where they terminate in a broad fascial expansion which embraces the lower part of the fore-leg. Another strong portion of this fleshy tegument spreads over the sides and loins, where it degenerates into a tendino-membranous layer, extending downwards as far as the penis, which it likewise invests with a carneo-membranous sheath. It likewise encases the buttocks and thighs in a strong covering of fleshy and tendinous fibres, which spreads downwards over the fascia lata to the hind leg.

In describing the other parts of the muscular system, it will be necessary to divide them into their appropriate regions, and in so doing, we shall follow the arrangement usually adopted in describing the human subject, beginning with the

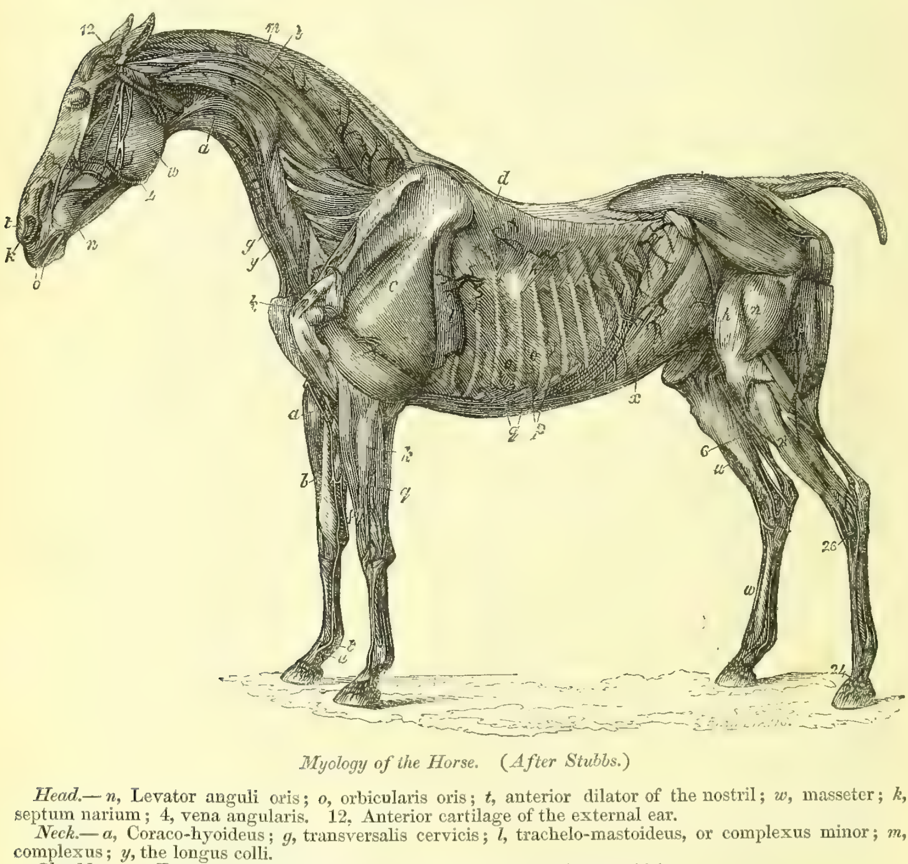
Proper muscles of the spine. — The long muscles of the spine, — viz. the spinalis and semi-spinalis dorsi, longissimus dorsi and sacro-lumbalis — present a disposition very similar to what occurs in the human subject.

The *spinalis dorsi* takes its origin from the spinous processes of the lumbar and posterior dorsal vertebræ, as well as from the broad fascia of the loins, and running forwards is inserted by distinct tendons into the spines of the anterior vertebræ of the back. Its continuation, the *spinalis cervicis*, is in the horse of great strength and importance: its origin commences from the second spine of the back, which origin is continued for about one third of the way down that spine towards its root: it arises likewise from the third dorsal spine and the ligamentum nuchæ; from these origins it runs forward to be implanted by strong and distinct tendons into the spines of the anterior cervical vertebræ.

The *longissimus dorsi* is situated immediately external to the spinalis, taking its origin from the common mass of muscle that arises beneath the lumbar fascia, as well as from the spinous processes of the loins and sacrum, whence it runs forward to be inserted by a double set of tendons into the transverse processes of the loins and back, and also into the posterior ribs near their angles. Its continuation, the *transversalis colli*, is likewise of considerable strength, but offers nothing worthy of remark.

The *sacro-lumbalis* arises, in conjunction with the latissimus dorsi, from the back of the sacrum, and also by flat tendons about

Fig. 501.



Myology of the Horse. (*After Stubbs.*)

Head.— *n*, Levator anguli oris; *o*, orbicularis oris; *t*, anterior dilator of the nostril; *w*, masseter; *k*, septum narium; 4, vena angularis. 12, Anterior cartilage of the external ear.

Neck.— *a*, Coraco-hyoideus; *g*, transversalis cervicis; *l*, trachelo-mastoideus, or complexus minor; *m*, complexus; *y*, the longus colli.

Shoulder.— *c*, Triceps extensor cubiti; *k*, tendon of the biceps flexor cubiti.

Forearm and anterior extremity.— *a*, *b*, *c*, Extensor carpi radialis; *k*, extensor digitorum communis; *q*, analogue of the extensor minimi digiti; 6, 9, ligaments; *t*, vena plantaris interna; *u*, nervus plantaris internus.

Trunk.— *d*, serratus minor posticus; *h*, serratus major posticus; *l*, serratus major anticus; *o*, external intercostals; *p*, internal intercostals; *q*, rectus abdominis; *x*, obliquus internus.

Hinder extremity.— *b*, glutæus medius; *h*, rectus femoris; *n*, vastus externus; *u*, *w*, 21, 26, 24, extensor digitorum pedis; 6. plantaris and gastrocnemius.

half the breadth of the muscle from the superior edge of all the ribs, except two or three of the most anterior; and its slips are inse ted by as many distinct tendons into the inferior edge of all the ribs, except two or three of the hindmost, and also into the transverse process of the seventh vertebra of the neck. The continuation of this muscle, the *cervicalis descendens*, offers nothing remarkable.

The *multifidus spinæ*, in the dorsal region arises by numerous tendinous origins from the transverse processes of the vertebræ of the back, loins, and sacrum, near their posterior protuberances, each slip running forwards to be inserted into the spinous process of the vertebra in front of that from which it derives its origin, the whole forming a thick mass, which fills up the hollow situated between the spinous and transverse processes. In the neck a similar disposition exists.

The *intertransversarii colli* take their origins from the roots of the oblique processes of the cervical vertebræ, and from between these and the transverse processes: in the horse they are of great strength and importance, running forwards to be inserted into the transverse processes of the vertebra in front of that from which they arise. In addition to the above there is a set of muscles named by Stubbs the *intervertebrales*, which do not exist in the human subject: these arise from the ascending oblique processes of the five inferior vertebræ of the neck, and from the space betwixt the oblique processes of the uppermost vertebræ of the back: they are each of them inserted into the lateral parts of the bodies of the vertebræ above their origin.

The *longus colli* is the only muscle, exclusively appropriated to the movements of the spine, situated in front of the spinal column. This muscle, in the horse, arises from the transverse processes of the third, fourth, fifth, and sixth vertebræ of the neck, from which origins it runs upwards to be inserted by distinct tendons into the anterior part of the bodies and transverse processes of the vertebræ above them, and into the anterior surface of the atlas.

The *quadratus lumborum* offers the same disposition as in the human subject.

The tail in quadrupeds, from its great development, requires for its movements a special set of muscles, of which scarcely any traces exist in the human subject. This organ in the horse is susceptible of three kinds of movements. It can be straightened or elevated, bent or brought downwards, and lastly carried to either side. These movements, again, by their combinations, produce secondary effects, so that the tail becomes susceptible of very extensive motions; and, in such quadrupeds as have this part very largely developed, it even supplies the place of a hand, so completely is it under muscular control.

In order to effect these different movements, three * distinct sets of muscles are employed, which are arranged upon the same plan as the long muscles in other parts of the spinal column; that is to say, they arise by numerous tendinous slips, and are inserted in a similar manner, the slips of origin and insertion running, of course, in opposite directions: the latter, moreover, are prolonged to a much greater extent than in the rest of the spinal column, and firmly bound down to the vertebræ by tendinous sheaths, so as to add as little as possible to the bulk of the tail.

The *muscles which raise or straighten the tail* are all situated upon its upper aspect: they are, first,

The *sacro-coccygeus superior* (*lombo-sus-caudien*). This muscle arises in the horse from the inferior or posterior edge of the third spinal process of the os sacrum, and from the spines, edges, and interspinal ligaments of the sacral vertebræ behind that point, as well as from those caudal vertebræ that are possessed of spinous apophyses. The fleshy mass formed from these origins gives off numerous slender tendons: the first of these is the shortest, and runs inwards to be inserted into the base of the first caudal vertebra, in which the articular apophyses are wanting. The second tendon is inserted in a similar manner into the succeeding vertebral piece; the third into the next, and so on to the end of the tail. The number of the tendons given off is, of course, determined by that of the vertebræ. Each tendon is lodged in a sort of ligamentous canal, which forms a sheath for it throughout its whole course. When these two muscles act in concert the tail is necessarily raised upwards.

The *interspinales superiores* (*spinalis obliquus; lombo-sacro-coccygien* of Vicq d'Azyr). These muscles are a continuation of the interspinous muscles of the spine; but as the spinous processes of the tail are short, and frequently replaced by two tubercles answering to rudiments of the oblique processes, these muscles are here disposed obliquely, being more widely separated posteriorly than they are in front.

The *muscles which depress the tail* or bend it downwards all take their origin in the interior of the pelvis, and are prolonged to a greater or less extent along the inferior aspect of the tail. These form, when completely developed, four pairs, or four pairs of series, of muscles.

1. The *ileo-coccygei* (*ileo-sous-caudien* of Vicq d'Azyr) arise from the internal or pelvic surface of the ossa ilei, and, forming an elongated fleshy belly in the interior of the pelvis, terminate beneath the root of the tail, which they will consequently depress with considerable force against the anus.

2. The *sacro-coccygeus inferior* (*sacro-sous-caudien*) is the antagonist of the sacro-coccygeus superior, above described, which in structure it exactly resembles. This muscle takes its origin from the inferior surface of the sacrum and of the transverse processes of those caudal vertebræ in which these processes are developed, by a fleshy belly which gradually diminishes in thickness, and termi-

* Cuvier, Anat. Comp. tom. i. p. 275.

nates by forming as many tendons as there are caudal vertebræ without transverse processes. These tendons are received into sheaths resembling those upon the upper surface of the tail, and are inserted successively into the base of each caudal vertebra, beginning about the seventh.

3. The *interspinales inferiores* (*sub-caudales, inter-coccygeus* of Vicq d'Azyr). These are situated beneath the mesian line of the tail. They commence underneath the articulation between the first and second caudal vertebræ, and form an elongated fleshy belly, which, in some quadrupeds that have the tail largely developed, become first of all implanted into V-shaped bones derived from the fourth, fifth and sixth vertebræ of the tail: they receive, moreover, from time to time additional fleshy slips, which go on continually diminishing in size, and give off tendons to be inserted successively into the inferior aspect of the base of each caudal vertebra.

4. The *pubo-coccygeus* (*pubo-sous-caudien*). This is a thin muscle, derived from the whole extent of the upper margin of the pelvis, and having the appearance of a fleshy membrane. the fibres of which are gradually collected into one point to be inserted beneath the tail into tubercles situated upon the base of the fourth and fifth vertebræ. The action of this muscle will produce an effect similar to that of the ileo-coccygeus.

The *muscles adapted to move the tail laterally* are arranged in two sets.

1. The *ischio coccygeus externus* (*ischio-caudien*) arises from the posterior or internal surface of the ischium, a little below and behind the cotyloid cavity, from which origin it runs backwards to be inserted into the transverse processes of the anterior caudal vertebræ. This muscle is improperly called by Stubbs the *levator ani*, because in the horse a few fibres of it are connected with the termination of the rectum.

2. The *intertransversales* (*intertransversal* of Vicq d'Azyr) extend in the form of musculo-aponeurotic layers over all the transverse processes that are developed in the caudal region, their tendons of insertion being most distinctly seen upon the upper surface of the tail.

In animals that have the muscular apparatus of the tail completely developed the muscles are found to consist of eight distinct sets, —viz., two superior, two lateral, and two inferior. In the horse some of these are deficient, or exist only in a rudimentary condition. To see them in their full state of development they must be examined in animals provided with long and mobile tails, such as the prehensile-tailed monkeys, the opossums, the lion, and, more especially, in the kangaroo and beaver.

Muscles derived from the spinal column which serve immediately for the movements of the cranium. — These have nearly the same origins as in the human subject, but are comparatively of much greater strength, owing to the inclined position of the head with respect to the vertebral column. They may be divided into such as proceed, 1st, from the atlas; 2nd, from the axis; and, 3rd, from the posterior cervical vertebræ and ligamentum nuchæ. To the first set belong —

1. The *rectus capitis posticus minor*, or rather *medius*, arising, as in the human subject, from the atlas; from this origin it runs to be inserted by a short and broad tendon into the occiput.

The other muscles belonging to the atlas — namely, the *rectus anticus*, the *rectus lateralis*, and the *obliquus superior* — offer the same position as in the man.

The muscles derived from the axis — viz. the *rectus posticus major* and the *obliquus inferior* — are likewise similarly disposed in all quadrupeds.

The muscles arising from the other cervical vertebræ are

The *complexus*, which, commencing from the upper oblique process of the third vertebra of the neck, continues its origin from all the oblique processes of the neck below that point, as well as from the upper oblique process of the first vertebra of the back, also by a pretty strong tendon from the transverse processes of the second and third dorsal vertebræ; from these origins it runs forwards to be inserted by a strong round tendon into the occiput close to its fellow of the opposite side: in this course it is connected by numerous tendinous processes with the ligamentum nuchæ. That portion of the complexus usually distinguished by the name of *digastricus colli* is in the horse undistinguishable as a distinct muscle.

The *trachelo-mastoideus*, or *complexus minor*, arises from the oblique processes of the third, fourth, fifth, sixth, and seventh cervical and first dorsal vertebræ, and from the transverse processes of the second and third vertebræ of the back; it runs forwards external to the last-mentioned muscles to be inserted by a strong tendon into the mastoid apophysis of the temporal bone. The above muscles are overlapped by the

Splenius capitis (*cervico-mastoiden*), which, arising by strong tendinous processes from the spinous processes of the two superior dorsal and two last cervical, and also extensively from the ligamentum nuchæ, runs forward to be inserted into the transverse processes of the fifth, fourth, and third cervical vertebra, and into the transverse ridge of the occipital bone. It is remarked by Cuvier that in carnivorous quadrupeds the splenius is not inserted into the transverse processes of the cervical vertebræ as it is in herbivorous animals and in the human subject, in which the latter portion is sometimes sufficiently distinct to obtain the name of *splenius colli* in contradistinction to the *splenius capitis*. It is likewise remarkable that in the camel, if the splenius exists at all, it is extremely thin and difficult to display by dissection.

Muscles of the ribs and sternum. — The muscles derived from and inserted into the ribs and sternum are found in all quadrupeds to have the same general arrangement as in the human subject. In the horse, their disposition is as follows, beginning with those whose office is to raise the framework of the chest and thus assist in inspiration.

The *scaleni* differ in no remarkable respect from the corresponding muscles in the human body. The same may be said of the *intercostal muscles*, the *levatores costarum*, the *serratus posticus superior* (*dorso-costien*), the *serratus posticus inferior* (*lombo-costien*), and the *triangularis sterni* (*sterno-costien*), the two latter of which must be regarded as depressors of the ribs, and consequently acting the part of muscles of expiration.

In all quadrupeds possessing a greater number of ribs, and consequently a more capacious thorax than man, the attachments of the *diaphragm* are found to be much further removed from the margins of the false ribs than in the human subject: nevertheless the position which it occupies, and its connections in the thoracic cavity, are similar in all mammiferous animals.

The *walls of the abdomen*, in the horse as in the generality of quadrupeds, are composed of five pairs of muscles, to which the same names are applicable as are bestowed upon them by the anthropotomist.

The *obliquus externus abdominis* (*costo-abdominien*) arises, by tendinous processes that indigitate with the origins of the serratus magnus, from the external surface of all the lower ribs, beginning at the fifth; and below the last rib it derives its posterior attachment from the fascia lumborum; from these origins, it runs backwards and downwards, terminating in a broad tendinous expansion, the terminations of which in the linea alba, os pubis, and Poupart's ligament, together with the formation of the external abdominal ring, are exactly as in the human subject.

The *obliquus internus* (*ileo-abdominien*) exhibits the usual arrangement, arising tendinous and fleshy from the crest of the ileum and pubic ligament, whence it mounts obliquely forwards to be inserted into the cartilages of all the lower ribs as far forwards as the ensiform cartilage of the sternum.

The *rectus abdominis* (*sterno-pubien*) is much more extensively developed in the horse than in human beings. Arising from the os pubis it passes forwards enclosed in its usual sheath to be inserted into the ensiform cartilage and into the cartilaginous terminations of the third, fourth, fifth, sixth, seventh, eighth and ninth ribs, and also into the sternum between the cartilages of the third and fourth ribs. There are even fleshy fibres derived from this muscle prolonged as far forwards as the articulation between the first rib and the sternum, which, by the old anatomists, was regarded as a distinct muscle, and named "musculus in summo thorace situs."

In many of the Carnivora the rectus abdominis is equally remarkable for its great length, and in some species it is even prolonged forwards to the very anterior extremity of the sternum. When the recti are thus largely developed the *pyramidales* do not exist.

Anterior extremity. Muscles of the shoulder. — It may readily be supposed that in the horse and other herbivorous quadrupeds not possessed of a clavicle, and, moreover, remarkable for the extreme simplicity of the structure of their scapular apparatus, these muscles undergo important modifications in their disposition and attachments, which it will be interesting to investigate. In the human subject the muscles specially appropriated to the movements of the shoulder are eight in number, — viz. the *serratus magnus*, the *pectoralis minor*, the *levator scapulæ*, the *rhomboideus*, the *trapezius*, the *omo-hyoideus*, the *subclavius*, and the *sterno-cleido mastoideus*, all of which concur in producing the various movements of which the human shoulder is susceptible. Of these, it will be observed, the six first belong exclusively to the Scapula, except the *trapezius*, which is inserted extensively into the clavicle; whilst the operation of the two last is upon the clavicle only.

In quadrupeds the shoulder is furnished with the same muscles as those which are met with in man, only they present differences in their proportions and attachments, which are dependent upon the structure of the skeleton, or the particular requirements of the animal; and, moreover, they are provided with an additional muscle, of which no vestiges appear in our own bodies. In the horse, the arrangement of the muscular apparatus of the shoulder is as follows.

The *trapezius*, in all quadrupeds destitute of clavicles, or in which these bones are but imperfectly developed, presents an arrangement very different from what exists in such as have the clavicles completely formed: that part which would in the latter case have been the clavicular portion, becomes confounded with the deltoid and with the cleido-mastoid (here a very distinct muscle from the sterno-mastoid). From the combination of these three, there usually results a single muscle, which is implanted immediately into the humerus, and which, from its attachments, might be named the *masto-humeralis*. It is this muscle which is named by Stubbs the *levator humeri proprius*, and its posterior part *musculus ad levatorem accessorius*; and by the French hippotomists *muscle commun de la tête de l'enclosure et du bras*. This clavicular portion of the trapezius is very distinct from the scapular portion, from which it is in many animals separated by the *trachelo-acromial* muscle, to be described further on.

In the horse, therefore, the Trapezius may be said to consist of that part only which is called the ascending portion in the human subject, and which is inserted into the posterior margin of the spine of the scapula. The *sterno-mastoid* is present, but the *levator anguli scapulæ*, the cleido-mastoid, and the clavicular portions of the *trapezius* and *deltoid* are all replaced by the muscular expansion above described, and which, taking its origin from the mastoid process of the temporal bone and from the transverse processes of some of the superior cervical vertebræ, passes downwards in front of the head of the humerus and descends along the inner surface of the forearm, into which it is ultimately inserted.

The muscle of the shoulder which is proper to quadrupeds may be named the *trachelo-acromialis* (*acromio-trachelien*, Cuv., *acromio-basilaire*, Vicq d'Azyr). It arises in the horse from the transverse process of the atlas and of the four following cervical vertebræ (in the generality of quadrupeds from the three uppermost only); from this origin it descends towards the shoulder-joint, making its appearance externally between the two divisions of the trapezius, which it separates; it then spreads out over the acromial portion of the scapula, and descends as far as the middle of the humerus, where it is inserted. Its action will, of course, be to draw the shoulder upwards and forwards. This muscle, which exists in all the mammalia, with the exception of the human species, would seem to be in special relation with the quadrupedal mode of progression; and, as Cuvier observes, affords a striking example of the difficulty of establishing a good nomenclature in comparative anatomy: in some animals, it derives its origin exclusively from the cranium; and, in others, from the upper or lower cervical vertebræ. Its mode of insertion is equally various; in the tapir it is implanted into the aponeurosis which covers the deltoid muscle; while, in the horse, it has its insertion into the middle portion of the humerus by two aponeurotic tendons, which embrace the brachialis internus muscle.

The *serratus major anticus* (*scapulo-costien*), in the horse, arises from the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and also from the external surfaces of the six superior ribs: its origins extending as far backwards as the insertion of the tendons of the sacro-lumbalis: from this extensive origin it passes backwards around the chest to be implanted into the base of the scapula, its insertion occupying nearly half of the internal surface of that bone. This muscle, Cuvier remarks, is much more extensively developed in quadrupeds than in the human subject; for, in all other mammalia, except in the orang-outang, it arises not only by digitations from the ribs, but also from the transverse processes of the vertebræ of the neck, an arrangement which becomes necessary in animals that walk upon four feet, in order to prevent the scapula from being pushed too far backwards towards the spine. This muscle, in fact, forms, with its fellow on the opposite side, a kind of sling, by which the trunk is suspended. The fact that it is equally extensive in its attachments in the Monkeys, is an additional proof that the usual mode of progression in these animals is on four feet: in these animals, indeed, the serratus magnus derives origins from all the cervical vertebræ, instead of from only a part, as in other mammifera. In the Cetaceæ that do not walk, and in the kangaroos which have their anterior limbs very small, the serratus magnus presents a corresponding feebleness of developement.

The *pectoralis minor* (*serratus minor anticus*) is, in the horse, represented by a muscle, which, arising from the sternum and from the first, second, third, and fourth ribs near their sternal terminations, runs upwards and backwards to be inserted into the superior costa of the scapula near the base of that bone; it also contracts tendinous attachments with the aponeurotic covering of the teres minor and other scapular muscles.

The *rhomboideus* arises, in the horse, entirely from the ligamentum nuchæ, and from the spines of the anterior dorsal vertebræ, whence it runs outwards to be affixed to the base of the scapula.

In monkeys and in the carnivorous quadrupeds the rhomboideus is continued upwards as far as the occiput, whence it derives an extensive origin; the occipital portion, indeed, is, in the Carnivora, separated from the rest so as to form a distinct muscle, called by some writers the *occipito-scapularis*, and, by Cuvier, "*rhomboïde de la tête*."

The *omo-hyoideus* is, generally, wanting in animals whose scapula presents no coracoid process: neither can there be any *subclavius* in animals that do not possess a clavicle: in the horse, however, the former of these is represented by a strong muscular fasciculus.

In this place it may be proper to notice the muscle named by the human anatomist *sterno-cleido-mastoideus*; but which, in the lower animals, is represented by two distinct muscles. One of these,

The *sterno-mastoideus*, or, as it might be named, sterno-maxillaris, arises, in the horse, from the anterior end of the sternum, and, running forwards strong and fleshy, is inserted by a flat tendon into the inferior maxilla underneath the parotid gland, sending, however, another tendon to be implanted into the root of the mastoid process.

The *cleido-mastoideus*, always a distinct muscle from the preceding, is, as we have seen above, in the horse and other non-claviculate quadrupeds, confounded with the clavicular portions of the trapezius and deltoid.

Muscles inserted into the humerus. — The movements of the humerus in the human body are effected by two sets of muscles: one derived from the trunk, the other from the framework of the shoulder. The former are the pectoralis major and latissimus dorsi; the latter, the supra-spinatus, the infra-spinatus, and the subscapularis proceeding from the surfaces of the scapula, and the deltoid, teres minor, teres major, and coraco-brachialis, which take their origins from the processes. In the horse and in other quadrupeds, various circumstances render modifications in the arrangement of these muscles indispensable.

The *pectoralis major* (*sterno-humerien*), in the horse, arises, first, from the aponeurosis of the external oblique muscle of the abdomen; secondly, from the two lower thirds of the sternum; and, thirdly, from the superior part of the sternum for about one-third of its length. The first of these portions winds round to be inserted into the internal aspect of the head of the humerus; the second ends in a fascia, which descends downwards over the fore-arm, while the third, running in a transverse direction over the inferior portion, is inserted into the humerus along with the "levator humeri proprius" between the biceps and the brachiæus internus.

In all those mammalia which are destitute of complete clavicles, even in the Cetacea, there is a part of the sternal portion of the pectoralis major, which is inserted perpendicularly into the humerus, that joins the corresponding portion of the opposite side to form the *muscle common to both arms*," by the action of which the two fore-legs are made to cross each other.

The *latissimus dorsi* (*lombo-humerien*), in the horse, and in other quadrupeds, exhibits the same arrangement as in the human subject: it is, however, in the lower animals powerfully assisted in its action by the massy muscle already described (*cutano-humerien*), formed by the panniculus carnosus, a strong tendon from which is inserted into the humerus along with that of the latissimus dorsi. Both are intimately connected with the tendon of the teres major, and from this combination of tendons arises one of the heads of the triceps extensor cubiti.

The *supra-spinatus*, the *infra-spinatus*, the *subscapularis*, the *teres major*, and the *teres minor* have, in all quadrupeds, the same arrangement as in the human subject, the only differences being dependent upon the shape and proportions of the scapula.

The *deltoid* in all animals having their clavicles imperfect or wanting, is necessarily modified in its disposition to a very considerable degree. We have already seen when speaking of the trapezius, that its clavicular portion is in such cases blended with the anterior division of that muscle: that part only which takes its origin from the scapula remains to be noticed. Where the acromion is well developed, the deltoid may be divided into two portions; one derived from the acromion, the other proceeding from the spine and subjacent surface of the scapula: these two portions unite, and, decussating each other, form a common tendon, which is implanted into the deltoid ridge of the humerus. As the acromion process diminishes in size, the acromial portion of the deltoid becomes enfeebled in like degree, until at length, as in the horse, where there is no acromial projection, that part of the deltoid arising from the spine remains alone. Under these circumstances, this muscle is directed forwards in nearly the same direction as the infra-spinatus, and, both from its position and office has been named by hippotomists the "*abductor longus brachii*."

The *coraco-brachialis* exists even in animals that have no coracoid process, in which case it takes its origin from a little tubercle situated upon the superior costa of the scapula. When the biceps arises by two heads, as in the human subject, the coraco-brachialis arises with the longer head by a common tendon; but when, as is the case in many quadrupeds, the biceps has but one origin from the humerus, the coraco-brachialis is in no way connected with that muscle.

Muscles of the forearm. — *Flexors.* — The *biceps*, in the generality of quadrupeds, has the same origins as in the human subject; one head arising from the neck of the scapula, the other from its coracoid process: these two heads uniting form a common tendon, which is inserted into the tubercle of the radius, and, by an aponeurotic expansion into the fascia covering the muscles of the forearm; but where the coracoid process of the scapula is deficient, as in the horse, and in the carnivora generally, the term "biceps" is no longer applicable to this muscle, seeing that it has but one origin from the margin of the glenoid cavity: in the rest of its course it is similarly disposed in all the mammalia.

The *brachiæus internus* (*humero-cubitien*) in all quadrupeds has the same arrangement as in the human subject. In the horse, the biceps and the brachiæus are by most writers named the "long and short flexors of the forearm."

Extensors. — The *triceps extensor cubiti* (*scapulo-olecranien*) is in the horse a muscle of prodigious strength, and consists of three portions similar to those named in the human anatomy the long extensor, the short extensor, and the brachialis externus (the great extensor, the middle extensor, and the short extensor of Bourgelat, and other writers on the anatomy of the horse). There is, moreover, a fourth portion, derived from the common tendon of the latissimus dorsi and teres major, by the intervention of which, it takes its origin from the inferior margin of the scapula.

The *anconæus* (*epicondylo cubitien*) exists in all quadrupeds.

As might be expected from the construction of the bones of the forearm, both the *pronator muscles* are in the Solipeda entirely wanting, as is the case in the Ruminantia and in the Pachydermata generally; nevertheless, in the elephant and in the hog-tribe the pronator teres is feebly developed; and, as the mobility of the bones of the forearm becomes more perfect, as in the Carnivora, Quadrumana and Marsupialia, both the pronators are found presenting the same arrangement as in the human body.

The *supinators* are quite obliterated in the Solipeda, as well as in the Ruminantia and Pachydermata.

Muscles of the carpus and metacarpus. — The muscles employed in bending the wrist are in our own persons the palmaris longus, the flexor carpi radialis longior, the flexor carpi radialis brevior, the extensor carpi radialis, the flexor carpi ulnaris, and the extensor carpi ulnaris; of these one only is inserted into the carpus, all the rest being attached to the metacarpal bones.

In all multi-digitate mammalia, such as the Quadrumana, Carnivora, Rodentia, and Edentata, these six muscles exist and are disposed pretty nearly as in the human race; but in the Pachydermata and Ruminantia there is but one flexor carpi radialis. In all the above multidigitate animals, the muscles derived from the external condyle, and its vicinity by their co-operation, approximate the back of the hand towards the forearm, or, in other words, are extensors of the fore-foot; while those derived from the internal condyle have a contrary effect, and act as flexors of the hand. Should the flexor and extensor of the same side of the limb act together, the hand will be bent laterally in the corresponding direction.

In the Solipeda, where the movements of the wrist are strictly limited to those of flexion and extension, the disposition of these muscles is considerably modified.

The *extensor carpi radialis* is here single, arising from the anterior part of the external condyle of the humerus, and from the external surface of that bone for a considerable distance: it forms a strong fleshy belly, terminating in a powerful tendon, which runs to be inserted into the base of the anterior surface of the metacarpal or cannon bone. This muscle, called by Bourgelat the "*extenseur droit anterieur du canon*," seems, from the extent of its origin, to represent the long supinator and the two radial extensors of the wrist combined, and all three made to cooperate in the extension of the wrist.

The *flexor carpi radialis* (*epitrochlo-metacarpien*) arises from the external condyle of the humerus, and is inserted into the posterior surface of the base of the cannon bone, forming the antagonist to the preceding muscle: this is the "*flechisseur interne du canon*" of Bourgelat.

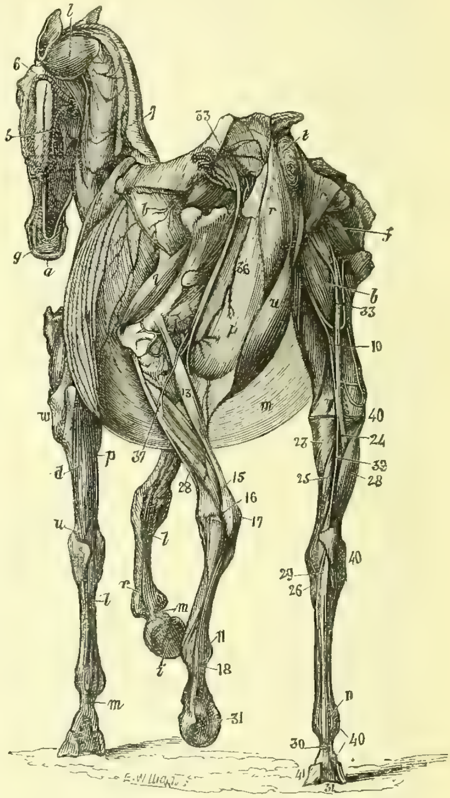
The *flexor carpi ulnaris* (*epitrochlo-carpien*) arises from the posterior part of the external protuberance of the os humeri, and also by a distinct head from the protuberance situated above the internal condyle; its tendon is inserted into the representative of the pisiform bone and also into the root of the rudimentary metacarpal bone beneath it: this is the "*flechisseur oblique du canon*" of Bourgelat.

The *extensor carpi ulnaris* (*cubito-sus-metacarpien*) arises from the posterior part of the external condyle of the humerus, and is inserted, like the preceding, into the os pisiforme, whence it is prolonged beneath the carpus, so as to perform the office of a flexor of the wrist ("*flechisseur externe*" Bourgelat.)

The *palmaris longus* does not exist in the Solipeda; nor is it found in the Pachydermata and Ruminantia, being in these orders of quadrupeds apparently combined with the flexor sublimis digitorum, as is likewise the case with this muscle in the bear, the badger, and the dog; in all other unguiculate quadrupeds it is disposed as in the human subject.

Muscles of the hand. — The *extensor communis digitorum* (*epicondylo-sus-phalangettien commun*). — This muscle in the horse is called by Bourgelat "*l'extenseur anterieur du pied*," and by Lafosse, "*l'extenseur du pied*:" it arises from the external condyle of the humerus and from the contiguous fasciæ, also from the upper and lateral part of the radius; its fleshy belly is strong, and terminates in a single tendon, which runs over the foot to be inserted into the last phalanx or coffin-bone, having previously given off a slip to join the tendon of the extensor minimi digiti.

Fig. 502.



Myology of the Horse. (*After Stubbs.*)

Head. — *a*, Orbicular muscle of the mouth; *g*, elevator of the chin; 5, arteria angularis; 6, arteria temporalis.

Neck. — *l*, Obliquus capitis inferior; 7, ligamentum nuchæ.

Trunk. — *m*, Transversalis abdominis; *t*, sphincter ani.

Left anterior Extremity. — *w*, Insertion of brachialis anticus; *d*, flexor profundus digiti; *p*, flexor carpi radialis; *u*, ligaments of the carpus; *l*, *m*, tendon of the flexor sublimis perforatus.

Right anterior Extremity. — *l*, *m*, Tendon of the flexor sublimis; *i*, insertion of flexor profundus into the coffin bone; *r*, flexor brevis digiti pedis.

Left posterior Extremity. — *p*, adductor magnus femoris; 7, vastus internus; *u*, gracilis; 13, 15, plantaris; 28, flexor longus digiti pedis; 16, external malleolus; 17, Internal malleolus; 18, division of the tendon of plantaris, to allow the tendon of the flexor profundus to proceed to its insertion at 31, into the coffin bone; 11, flexor brevis digiti pedis; 36, obturator artery; 37, nerves to the tibialis anticus.

Right posterior Extremity. — *c*, Tranversalis penis;

f, glutæus internus; *b*, iliacus internus; 10, vastus internus; 33, sciatic nerve; 23, poplitæus; 25, 26, tibialis posticus; 28, 29, 30, 31, flexor longus digiti pedis; 24, poplitæal nerve; 38, posterior tibial nerve; 40, articular ligaments of the knee ankle and pastern joints; 26, insertion of the tendon of the tibialis posticus into 29, that of the flexor longus digiti pedis; 11, flexor brevis digiti pedis; 31, insertion of the tendon of the flexor longus into the coffin bone; 41, internal cartilage of the hoof.

The *extensor proprius minimi digiti.* — In the horse this muscle is represented by two muscles. One of these, called by Bourgelat the *lateral extensor of the foot*, and by Lafosse *the extensor of the pastern*, is inserted by the intervention of a strong tendon into the side of the first phalanx of the solitary toe that forms the foot. The second muscle, placed between the above and the preceding muscle, furnishes a similar tendon, which, after passing in front of the carpus, becomes united at an acute angle with that of the former, the two co-operating with each other in extending the foot.

In the Ruminantia likewise this muscle is disposed after two different manners. In the Cervidæ or deer tribe, in which the rudimentary toes are capable of distinct movements, it furnishes two tendons to the two outer toes; whilst in oxen, goats, sheep, and antelopes its tendon presents a double insertion — one into the posterior aspect of the outer finger, the other into the tendon of the extensor communis.

The *extensor proprius indicis* and the two long extensors of the thumb are, in all the ungulate quadrupeds, entirely wanting.

The *abductor longus pollicis* is present in all the mammalia, even in the Ruminantia and the Solipeds. In the horse its tendon is implanted into the internal surface of the base of the cannon bone, so that it thus becomes an extensor of the foot (*l'extenseur oblique du canon* of Bourgelat).

The *flexor digitorum sublimis perforatus* and the *flexor profundus perforans.* — In the horse these muscles arise in common from the internal protuberance of the os humeri, and the two are confounded together for a considerable distance, when the two muscles separate to form two distinct tendons; of these, that belonging to the flexor sublimis runs beneath the annular ligaments of the carpus, to be inserted into the base of the great pastern bone previously dividing to give passage to the tendon of the profundus on its way to be implanted into the last phalanx or coffin bone of the foot.

In the ungulata the *small muscles of the hand* would evidently be useless, and accordingly in the horse all traces of them are lost, their place being supplied by the peculiar structure of the foot, to be described further on.

Posterior Extremity — Muscles of the Pelvis. —The muscles specially belonging to the pelvis are the *quadratus lumborum* and the *psoas parvus*, which in quadrupeds offer precisely the same arrangement as in man.

Muscles inserted into the os femoris —These are similarly disposed in all the Mammifera possessed of a pelvic extremity, the only differences observable being in their proportionate sizes. In the Solipeda the analogue of the *glutæus maximus* is so small, in comparison of the two other glutæi, that it is named by Bourgelat "*le petit fessier*," and by Stubbs the *glutæus externus.* In the human subject the comparative large size of this muscle is rendered necessary in consequence of the erect attitude of the body, which it principally assists in maintaining; whilst in quadrupeds, from the horizontal position of their bodies, it becomes of very secondary importance. In the horse it is a comparatively slender muscle, deriving its principal origin from the sacral fascia, but also reinforced by a long slender fasciculus, which descends immediately from the upper portion of the ileum. Its insertion is into the third trochanter and external rough surface at the upper part of the thigh bone, and also by strong tendinous aponeuroses into the fascia lata.

The *Glutæus medius* is the principal muscle in this region; it arises extensively from the sacro-iliac aponeurosis, and from the external surface of the ileum, from which origin it runs downwards and forwards to be implanted into the outer surface of the great trochanter, and is, moreover, prolonged, by means of a strong posterior fasciculus, towards the lower extremity of the femur. From this latter circumstance, as well as from its preponderating strength, the glutæus medius may be regarded as being, *par excellence*, the kicking muscle in these quadrupeds which instinctively have recourse to this mode of defence as best suited to their organization.

The other muscles inserted into the great trochanter — namely, the *glutæus minimus*, the *quadratus femoris*, the *obturator externus*, the *obturator internus*, the *gemelli*, and the *pyramidalis* —present in all quadrupeds a disposition similar to that which they have in the human body.

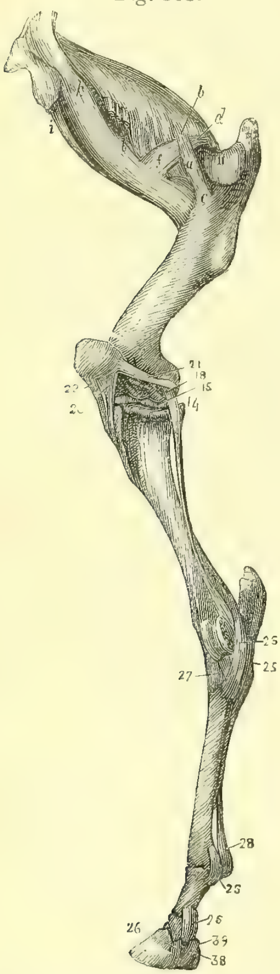
The muscles passing between the pelvis and the lesser trochanter, and also those that arise from the pubis to be implanted into the internal surface of the thigh, in the generality of quadrupeds, correspond very accurately with those of man. In the horse these are the *psoas magnus*, the *iliacus*, the *pectinæus*, and the *triple adductor*, none of which offer any peculiarity worthy of remark.

The *flexor muscles of the leg* are the *biceps flexor cruris*, the *semimembranosus*, the *semitendinosus*, the *sartorius*, the *gracilis*, and the *poplitæus*, all of which are enclosed by the dense fascia of the thigh, or fascia lata, which is kept tense by the action of a special muscle named the *tensor vaginæ femoris.*

The last-named muscle, called also the *musculus fasciæ latæ* (*ileo-fascien*) arises in the horse from the anterior portion of the crest of the ileum, whence it descends obliquely downwards, enclosed between two layers of the fascia, covering the thigh, into which it is strongly inserted.

The *extensor muscles of the thigh* — viz. the *biceps* (*ileo-rotulien*), the *vastus internus*, the *vastus externus*, and the *cruralis* — offer in all quadrupeds the same general disposition as in man, the three last forming one great common muscle (*trifemoro-rotulien*). The anterior margin of the thigh in the horse and in other quadrupeds is formed by the *sartorius* (*ileo-pretibien*), which here, from its position and office, has been named by hippotomists the "*long adductor of the thigh.*"

Fig. 503.



Deep muscles of the thigh and ligaments of the posterior extremity of the Horse.

a, b, c. A muscle named by Stubbs "*musculus parvus in articulatione femoris situs:* it arises by a flat tendon (*b*), from above the tendon of the *rectus cruris* (*d*), and is inserted tendinous into the os femoris (*c*); *i, k, l, iliacus internus.* The small numerals indicate the principal ligaments of the limb.

The *biceps* (*ischio-peronien*) in the horse and the greater number of quadrupeds, not even excepting the quadrumana, arises by a single origin, which is derived from the ischium, and the neighbouring ligaments and fascial expansions. This muscle covers a large proportion of the outer surface of the thigh: its principal insertion is into the head of the fibula, but it likewise throughout its whole length contracts extensive and important attachments with the fascia lata, so that it also becomes a powerful extensor of the thigh. There is moreover, in the horse and in the Ruminantia, a distinct portion of the biceps derived from the sacro-sciatic aponeurosis, the fibres of which are directed obliquely from before backwards, which, meeting the ischiatic portion at an angle, form with it a kind of raphe, which is prolonged for some distance. This muscle is called by Bourgelat the "*vastus longus*" of the thigh.

The *gracilis* (*pubio-pretibien*) is in all quadrupeds a very considerable muscle, more especially in such as have the thigh much shortened, as is the case in the horse, and the ungulata generally. It is called by Bourgelat the "*short adductor of the thigh,*" whilst he gives the name "*gracilis*" to the semitendinosus.

The *semimembranosus* (*ischio-sous-tibien*) and the *semitendinosus* (*ischio-pretibien*) have in all quadrupeds the same origin and general arrangement as in man; but both of them are in the lower animals inserted into the tibia by a broad aponeurosis. It must also be remarked that their insertion extends much lower down than in the human subject, a circumstance which causes the leg to be permanently kept in a semiflexed condition; and is one of the great obstacles to their walking in an upright position. Even in the Quadrumana these muscles have their insertions very low down in the leg.

The *poplitæus* has nothing remarkable in its disposition.

Muscles implanted into the foot. The *gastrocnemii* (*bi-femoro-calcanien*) and the *solæus* (*tibio-calcanien*) are less considerable muscles, as regards their comparative size in quadrupeds, than in the human race: nevertheless their general disposition is invariably the same as in man. In the *Solipeda*, the *solæus* is remarkably slender and feeble.

The *plantaris* (*femori-calcanien*). — In the Solipeds this muscle is remarkably developed, so much so indeed as apparently to represent the flexor sublimis. In the horse this muscle arises under the external head of the gemellus from a large fossa in the os femoris above the external condyle: its tendon is continued downwards, and runs over the extremity of the os calcis, where it is enclosed in a sheath formed by strong ligaments, which prevent it from slipping out of its place; passing on from this point, it divides, to be inserted upon each side of the posterior surface of the great pastern bone towards its inferior extremity, here giving passage between its two insertions to the tendon of the long flexor of the toe, which it serves to bend down closely to the pastern when the fetlock joint is bent, thus seeming to perform the functions both of the *plantaris* and of the short flexor of the toes.

The *tibialis anticus.* — In the Ruminantia and in the Solipeds, the *tibialis anticus* is in-planted into the anterior surface of the base of the metatarsal or cannon bone, so as to be simply an extensor of that portion of the foot which in these animals is usually misnamed the leg.

The *tibialis posticus* is altogether wanting in the Solipeds, as also in the Ruminantia and the hog-tribe.

The three *peronei* are, in the horse, represented by a single muscle, the tendon of which becomes conjoined with that of the long extensor of the digit, with which, when in action, it co-operates.

Muscles inserted into the digit. — The abductors and adductors* are the *abductor pollicis*, the *adductor obliquus pollicis*, the *adductor transversalis*, the *abductor minimi digiti*, and the *interossei*.

The *flexor muscles* in the horse are necessarily reduced to a state of extreme simplicity ; the short flexor communis is entirely wanting ; the *plantaris*, as described above, considerably increased in importance, has a double insertion into the base of the great pastern bone, and presents a similar disposition to that of the flexor perforatus in digitate quadrupeds, while the *flexor communis longus perforans*, here reduced to a single tendon, appropriated to the solitary toe, passes on as usual to be inserted into the last phalanx.

The *flexor longus pollicis* exists both in the Ruminantia and Solipeda, notwithstanding the total absence of a thumb in these animals ; but, instead of its usual destination, it here becomes affixed to the tendon of the flexor communis perforans, to which it forms a powerful auxiliary.

The *extensor muscles* of the toes in all digitate quadrupeds, provided with a representation of the great toe in the human foot, resemble those of man : in other animals there are some peculiarities that require notice. In the Quadrumana, the three muscles found in the human foot are present ; but in addition to these there is a proper *abductor of the thumb* (*adductor*, as it would be called by the anthropotomist), situated upon the inner side of the extensor pollicis longus, of which no traces exist in mankind.

Where the inner toe is wanting, as in the dog and the rabbit, the extensor pollicis is likewise deficient.

In the cloven-footed quadrupeds there is a proper extensor to the inner toe representing that of the thumb, and the peroneus longus, which is inserted into the external toe, performs the office of extending that also : there is moreover in Ruminants a long abductor of the thumb, the tendon of which is inserted close to that of the tibialis anticus

In the Solipeds, the *extensor communis* (*peroneo-sus-onguien*) terminates in a single tendon, which is inserted into the dorsum of the last phalanx of the foot: it receives, however, in transitu, a few fleshy fibres derived from the cannon bone, which represent the *extensor brevis* of unguiculate quadrupeds.

In the Solipeda, as might be expected, the *abductors and adductors* of the toes are entirely wanting.

Muscles which act immediately upon the lower jaw. — These are the *masseter*, the *temporal*, and the two *pterygoidei*, which in all quadrupeds have the same general arrangement as in human beings.

Muscles of the os hyoides. — The os hyoides of the Solipeds is constructed in accordance with a plan common to the Ruminants, and many Pachydermatous quadrupeds. Its body is arched and broad, presenting in the middle of its fore part a simple tubercle, and a tolerably long apophysis. It is consolidated with the superior cornua, which together form a very open arch. The single piece forming the anterior cornu is articulated to a rounded tubercle, situated just in front of the union between the posterior cornua and the body of the os hyoides, so as to admit of a considerable degree of motion in this joint. At its termination it is connected to the styloid process, which is very long and slightly forked.

The movements of the os hyoides are effected by numerous muscles, derived from several sources, the general arrangement of which, in most quadrupeds, conforms pretty nearly with what occurs in the human species.

The *sterno-hyoideus* exists in all quadrupeds, or, at least, is represented by a muscle of correspondent effect, derived from the sternum. In the Solipeda and in Ruminants, the sterno-hyoideus and the sterno-thyroideus form but a single muscle, which divides, to be inserted into both the larynx and os hyoides.

The *omo-hyoideus* in the horse is a very strong muscle, resembling in its origin that of the human subject ; but in some ruminants, as, for example, in the sheep, the analogue of the omo-hyoideus is derived from the transverse processes of the inferior cervical vertebræ.

The *genio-hyoideus* and the *mylo-hyoideus* have nearly the same arrangement in all mamiferous quadrupeds.

In the horse, all three of the above muscles are present. The *stylo-hyoideus* furnishes a sheath to the longer portion of the digastricus, and extends from the furcate extremity of the styloid bone to the base of the posterior corner of the os hyoides : this is the "*grand cerato-hyoidien*" of Gerard. There is also a "*cera-toidien lateral*" (*cerato-hyoideus*) of Girard, extending between the corner of the os hyoides and that of the thyroid cartilage.

Thirdly, there is the *mastoido-styloideus* (*stylo-hyoidien* of Gerard), a short thick muscle, derived from the long pyriform apophysis of occipital bone, whence it descends towards the angle of the styloid bone, into

* In comparative anatomy, owing to the permanently prone condition of the hand and foot of animals, it is impossible to employ the terms abductor and adductor, external and internal, &c., in the same sense as the anthropotomist: by *abductors* we therefore mean muscles which separate the external from the middle fingers, by *adductors* those which bring the fingers more closely together.

which it is inserted, above the origin of the stylo-hyoideus.

The other muscles of this region exhibit no peculiarities worthy of notice.

The muscles of the tongue, of the palate, and of the larynx, are in most quadrupeds strictly comparable to those of the human species.

Muscles of the Face. — These, from the conformity of their general arrangement with what exists in man, are distinguishable by the same names as are employed in human anatomy.

Fig. 504.

Facial Muscles of the Horse. (*After Sir Charles Bell.*)

a, orbicularis palpebrarum; *b, d*, cutaneous slips which raise the outer and the inner commissures of the eyelids; *c*, depressor of the lower eyelid; *e*, zygomaticus; *f, g*, levator anguli oris alæque nasi; *h*, elevator of the upper lip; *i*, dilator narium; *k*, nasal cartilage; *l, m*, orbicularis oris; *n*, masseter.

The *epicranius*, or *occipito-frontalis*, exhibits the usual origin from the posterior part of the cranium, whence, running forwards, it covers the skull with its tendinous aponeurosis, and, in front, spreads in muscular slips upon the forehead, some of which (*fig.* 504. *l*) extend downwards, to spread over those of the orbicularis palpebrarum.

Situated upon the outer side of the orbit there is another descending slip of muscle (*fig.* 504. *d*), apparently derived from the lateral muscle of the cartilage of the ear which, by elevating the external canthus of the eye, contributes much to the expression of that organ.

The *orbicularis palpebrarum* (*fig.* 504. *a a*) arises, as in the human subject, from the commissural ligament at the inner canthus of the eyelids, whence it winds round the orbit, its lower fibres receiving attachment from the os lachrymale.

Internal to the last-named muscle are a few fibres, that represent the *corrugator supercilii.*

The *Levator anguli oris* (*fig.* 504. *f, g*) is, likewise, extensively inserted into the upper lip and margin of the nostril: it has two origins, derived from the surface of the superior maxillary bone, between which the lateral dilator of the nostril and upper lip passes to its destination.

The *depressor of the lower eyelid* (*fig.* 504. *c*) is a short muscular slip, the use of which is sufficiently indicated by its name.

The *zygomaticus* (*fig.* 504. *e*) is a depressor of the external angle of the eye, as well as an elevator of the corner of the mouth, its fibres being intermixed with those of the orbicularis palpebrarum, as well as of the orbicularis oris.

The *long dilator of the nostril, and elevator of the upper lip* (*fig.* 504. *i*), arises at a little distance below the inferior margin of the orbit; and, passing between the two origins of the levator anguli oris, terminates in a tendon, which becomes connected with that of the opposite side, and then spreads out in front of the upper lip.

From the tendon of the last muscle arises the *anterior dilator of the nostril* (*fig.* 504 *h*), which, acting upon the interior nasal cartilage, powerfully expands the aperture of the nose.

The other muscles — viz. the *orbicularis oris*, the *levator labii superioris*, the *elevator of the chin*, and the *depressors of the lower lip, and angle of the mouth* — need no particular description.

Alimentary Apparatus. *Teeth.* — The dental formula common to the Solipeda is as follows: —

Incisors $\frac{3—3}{3—3}$, canine $\frac{1—1}{1—1}$, premolars, $\frac{3—3}{3—3}$, molars, $\frac{3—3}{3—3}$ The canine teeth, however, it must be observed, only exist in the male sex.

The *incisor teeth*, in the generality of herbivorous quadrupeds, are bevelled off posteriorly, so as to present in front chisel-like cutting edges; but in the Solipeds, when young, the lateral incisors are furnished with two cutting edges, one in front and the other behind, from which circumstance those central fossæ are produced which, as we shall see further on, furnish important testimony relative to the age of the animal.

The *canine teeth*, here called "*tusks*," or "*tushes*," are always of very moderate dimensions, and their points, at an early age, become flattened and blunt. Those of the upper jaw are separated from the incisors by a considerable interval; and a similar interspace also exists, but to a less extent, in the lower jaw.

The *molar teeth* of the horse are of a prismatic form, their grinding surfaces being marked with four crescents of enamel in the lower jaw, and with five in the upper: these crescentic patches in the upper jaw have their concavities turned outwards, but in the lower jaw in the opposite direction. The teeth of the horse are, moreover, distinguishable from those of the ox and some other Ruminants, which they resemble in their general appearance, from the circumstance that, in the latter, the crescentic patches of enamel are arranged in pairs, and are placed parallel to each other; whilst in the horse they are situated alternately, the first of the inner margin of the tooth corresponding to the interval between the two of the outer margin.

Professor Owen * observes, that the character by which the horse's molars may be best distinguished from the teeth of other Herbivora corresponding with them in size, is the great length of the tooth before it divides into fangs. This division, indeed, does not begin to take place until much of the crown has been worn away; and thus, except in old horses, a considerable portion of the whole of the molar is implanted in the socket by an undivided base. The deciduous molars have shorter bodies, and sooner begin to develope roots; but in these, or in an old permanent molar with roots, the pattern of the grinding surface, though it be a little changed by partial obliteration of the enamel folds, yet generally retains as much of its character as to serve, with the form of the tooth, to distinguish such tooth from the permanent molar of a Ruminant.

A knowledge of the structure and history of the teeth of the horse becomes additionally important, from the circumstance that it is from the condition of the dental apparatus that an estimate may be formed concerning the age of the animal; and, in order to understand the data thus afforded, it will be necessary to consider the structure of these organs rather more closely.

The incisors †, when the permanent teeth are first completely developed, are arranged close together, forming the arc of a circle at the extremity of both jaws; they are slightly curved, with long simple sub-trihedral fangs, tapering to their extremity. The crowns are broad, thick, and short; the contour of the biting surface, before it is much worn, approaching an ellipse. These teeth, if found detached, recent, or fossil, are distinguishable from those of the Ruminants by their greater curvature, and from those of all other animals by a fold of enamel, which penetrates the body of the crown from its broad flat summit, like the inverted finger of a glove. When the tooth begins to be worn, the fold forms an island of enamel, inclosing a cavity partly filled with cement, and partly by the discoloured substances of the food, and is called "*the mark*." In aged horses the incisors are worn down below the extent of the fold, and "the mark" disappears. The cavity is usu-

ally obliterated in the first, or mid-incisors, at the sixth year; in the second incisors at the seventh year, and in the third, or outer incisors, in the eighth year, in the lower jaw. It remains longer in those of the upper jaw, and in both the place of the "mark" continues for some years to be indicated by the dark-coloured cement, even to about sixteen years old. At this period the worn summits of the incisors present a subtriangular form.

The canine teeth are small in the horse, and rudimentary in the mare; the unworn crown is remarkable for the folding in of the anterior and posterior margins of enamel, which here includes an extremely thin layer of dentine. The representative of the first premolar in the first set of teeth is a very small and simple rudiment, and is soon shed. The three normal premolars are as large and complex as the true molars, the anterior one being usually the largest of the series in the upper jaw.

Salivary Glands. — The salivary apparatus in the Solipeda is very extensive, perhaps more so than in any other class of quadrupeds, consisting of large glandular masses divided into numerous lobes and lobules of a pale colour, and but loosely connected together by cellular tissue.

The *Parotid Glands* in the horse constitute a secreting apparatus, the bulk of which is extremely remarkable. Each of these glands extends from the external meatus auditoreus along the side of the head and of the lower jaw, as far forwards as the masseter muscle, and at the same time stretching deeply inwards as far as the side of the trachea. This enormous glandular organ may be considered as composed of three principal portions: each furnishing its excretory duct, which, however, soon unite to form a common canal, which at first descends within the angle of the jaw, whence, winding round the anterior edge of the masseter, it mounts up externally as far as the buccinator muscle, which it perforates nearly opposite the fourth molar tooth of the upper jaw, its internal orifice being situated in the centre of a prominent papilla.

The *Submaxillary Glands* are much smaller than the parotids. Posteriorly they consist of a thick globular portion, which is adherent to the inner surface of the parotid, but as they advance forwards, they become considerably attenuated, each terminating in its appropriate duct. The latter is of considerable length, and, after passing the sublingual gland, with which it contracts some attachments, opens into the mouth at a little distance behind the canine tooth, its opening being in the immediate vicinity of a papilla that seems to form a kind of valve at its orifice.

The *Sublingual Glands* are smaller than the preceding, and are of an oblong shape: they pour the saliva that they secrete into the cavity of the mouth through numerous orifices arranged in several rows on each side of the tongue.

In addition to the above large glandular organs, there remain to be noticed the *Molar Glands*, consisting of numerous detached granular-looking bodies of a lenticular shape situated beneath the mucous membrane that lines the buccinator muscle, and the inner surface of the superior maxillary bone behind which they mount up into the zygomatic fossa to within a little distance of the abductor muscle of the eye.

Pharynx. — The pharynx in quadrupeds generally presents a structure very similar to that of the human race, and may be said to be composed of analogous muscles: nevertheless its horizontal position in these animals renders the necessity for muscular exertion during deglutition greater than in man; and, accordingly, these fibres are not only stronger in quadrupeds than in our own persons, but sometimes additional muscles are met with, by the aid of which the action of swallowing is facilitated.

In the horse, the muscle which represents the *middle constrictor of the pharynx* might more properly be called the *pterygo-palato-*

pharyngeus *, its fibres descending from the pterygoid and palate bones, along the sides of the pharynx, around which they wind obliquely, uniting in the middle line upon its posterior surface, where they form a thick muscular layer.

The *inferior constrictor*, or *thyro-pharyngeus*, is equally broad and strong, its fleshy fibres taking nearly the same direction as they proceed towards the back of the pharynx, where they join by a median raphe.

In addition to the above, there is a *crico-pharyngeus*, arising from the posterior and inferior margin of the cricoid cartilage, whence its fibres extend obliquely upwards along the sides of the pharynx.

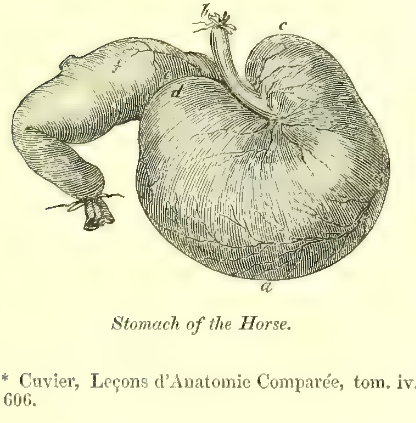
The analogue of the *stylo-pharyngeus* is, in the Solipeds, a cylindrical muscle derived from the styloid bone, and, running from behind forwards upon the sides and upper part of the pharynx, mixes its fibres with those of the superior constrictor — its action is to raise the commencement of the pharyngeal sac, which it at the same time dilates and draws backward.

There is likewise a small muscle derived from the middle part of the styloid bone, the fibres of which run backwards and inwards, so as to meet those of the muscle last mentioned.

Lastly, there are two other muscles, the fibres of which take a longitudinal direction. One of these, the *pharyngeus proprius*, arises from the tendinous middle line that extends from below the insertion of the stylo-pharyngei, and is prolonged downwards along the posterior and lateral walls of the œsophagus: the other, the *aryteno-pharyngeus*, is a small muscular band proceeding from the back part of each arytenoid cartilage, and running down the front of the œsophagus towards the stomach.

Stomach. — In all the Solipeda the stomach is simple, and presents little remarkable in its shape. The œsophagus (*fig.* 510. *b*) is inserted at a very acute angle into its smaller curvature, which is, as it were, folded upon itself. The cardiac cul-de-sac (*c*) is very capacious,

Fig. 510.



Stomach of the Horse.

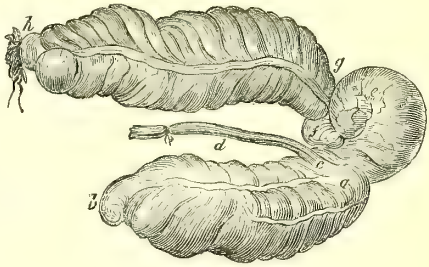
* Cuvier, Leçons d'Anatomie Comparée, tom. iv. p. 606.

and is lined throughout internally with a thick cuticular layer continuous with the lining of the œsophagus, and extends nearly as far as the middle of the stomachal cavity, where it terminates abruptly by a prominent indented edge, the interior of the pyloric half of the viscus (*a*, *d*) presenting the usual villous mucous surface. The muscular coat of the stomach consists of several superimposed layers of fibres that cross each other in different directions, some of them being apparently derivations from the muscular bands of the œsophagus; and it is doubtless the contractions of these muscular bands, in conjunction with the obliquity of the entrance of the œsophagus, that renders the act of vomiting impossible in these animals.

The alimentary canal in the Solipeds is short in comparison with that of the Ruminants and some other herbivorous quadrupeds; but this want of length is perhaps more than made up for by the enormous capacity of the large intestine, which, on first opening the body of one of these animals, seems of itself to occupy the whole of the abdominal cavity.

Commencing from the pylorus, the duodenum (*fig.* 510. *f.*) is found to be considerably

Fig. 511.

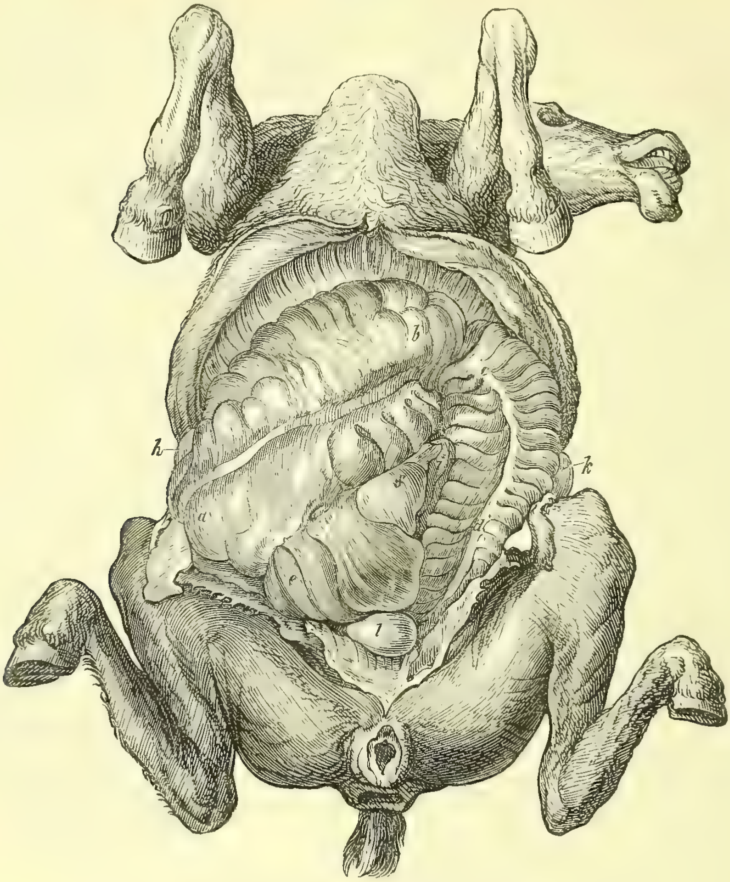


Caput Coli &c. of the Horse.

dilated; but its diameter soon contracts, and the rest of the tract of the small intestines is of pretty equable dimensions throughout, or if it presents constrictions here and there, they disappear when the gut is distended with air. The iliac portion of the small intestine (*fig.* 511. *d*) terminates in a cæcum of enormous bulk (*fig.* 511. *a*, *b*, *c*, *e*, *f*), which is separated from the commencement of the colon by a deep constriction (*g*): the colon itself is throughout its entire extent proportionately voluminous, commencing in the right flank: its ample folds (*fig.* 512. *a*, *b*) mount upwards as far as the diaphragm, whence they descend again, forming a viscus of vast capacity as far as the left iliac region, where, becoming gradually contracted in its dimensions, it terminates in the rectum. The ascending portion of the colon (*a*, *b*) is separated from the descending part (*c*, *d*) by a constriction; and the latter forms a third remarkable dilatation before it ends in the rectum. The whole colon is puckered up into huge sacculi by three longitudinal muscular bands, which terminate where the rectum begins, the last-named division of the alimentary canal presenting only a few pouches of comparatively small size, in which the fæces become moulded into balls preparatory to their expulsion.

When in a state of moderate distension, the

Fig. 512.



Colon of the Mare in Situ.

small intestines of an ordinary size are found to measure about fifty-six feet in length from the pylorus to the cæcum, with a circumference varying according to the state of contraction of the bowel from two inches and a half to six inches. The cæcum is about two feet and a half long, and about two feet in circumference at its broadest part; but towards its blind termination it assumes a conical form, and terminates in a point (*fig.* 511. *b*). Above the ileo-cæcal junction, the intestine forms a cul-de-sac (*fig.* 511. *e*), which is bent upon itself so as almost to resemble a second cæcum separated from the rest of the colon by a deep contraction, and there is, moreover, sometimes a third globular cavity, situated as shewn in *fig.* 511. *f*: but this is not constantly present.

The enormous colon (*fig.* 512. *a*, *b*, *c*, *d*), which seems of itself to occupy the whole abdominal cavity, is divided into two portions: — the first (*a*, *b*) is about 2 feet 3 inches long, and, at least, two feet in circumference; the second portion (*c*, *d*) is of nearly the same dimensions; but towards its termination, its circumference diminishes to 10 inches, and the continuation of the bowel retains that size for the length of a couple of feet, when it again enlarges to a circumference of 2 feet 4 inches before its termination in the rectum.

The entire length of the colon and rectum taken together is 21 feet, which, added to the length of the small intestines, gives a total length of 77 feet for the intestinal canal, exclusive of the cæcum.

Liver. — This viscus in the horse is divided pretty equally between the left and the right sides of the body. It is divided into four lobes, measures about a foot and a half in its greatest diameter, and weighs between four and five pounds. There is no gall-bladder; but the hepatic duct is extremely capacious, and evidently forms a receptacle for the biliary secretion.

Spleen. — The spleen of the horse has the shape of an elongated triangle, situated, obliquely, upon the left side of the stomach; its base pointing upwards and backwards, and its apex downwards and forwards; it is about 9 inches long, 4 inches broad at its widest part, and three-quarters of an inch in thickness. Its weight is about twelve ounces.

The *pancreas* is of an irregular shape, appearing to be made up of three branches — the shortest of which terminates at the duodenum; of the other two, one extends beneath the right, and the other reaches as far as the left kidney: these three branches form, by their union, a flattened mass, about half an inch in thickness, which may be called the body of the pancreas. There is nothing remarkable in the arrangement of its excretory duct.

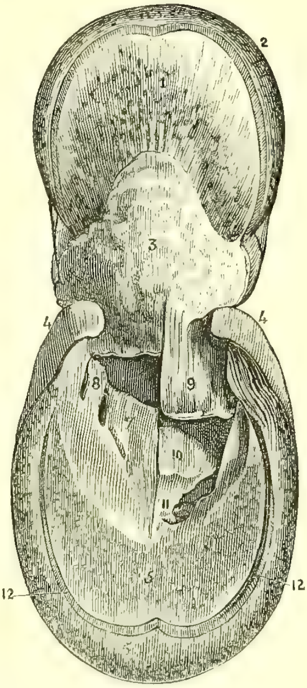
Circulatory Apparatus. — The structure of the *heart* and the general arrangement of the *arterial and venous systems* offer no peculiarities worthy of notice.

Structure of the Horse's Foot.—The mechanical structure of the foot of the horse demands to be considered at length, for in whatever point of view this part of their economy is regarded, either as a simple instrument of progression, or a curious piece of anatomy, it will be found equally deserving the study of the physiologist and of the veterinarian. Numerous writers have accordingly devoted their attention to this subject, both on the continent and in our own country; but their descriptions are, unfortunately, so mixed up with terms of farriery and stable jargon, that the anatomist finds considerable difficulty in deciphering their elaborate disquisitions. Among the most philosophical English treatises are those of Professor Coleman and Mr. Bracy Clark, to both of whom we shall be indebted for many of the following observations.

Horny hoof. — The whole exterior conical covering of the horse's foot, called in technical language the "wall of the hoof," is formed of a dense horny substance, which in shape resembles a hollow cone obliquely truncated at its upper part, so that the hoof is deepest or highest in front of the foot, diminishing in this respect as it recedes backwards towards the "quarters;" it then loses, to a considerable extent, its conical shape, and becomes nearly upright, especially on the inside or inner quarter, still growing narrower or lower to the posterior extremity of the foot, where, at first sight, it appears to terminate by mixing with the substance of the "frog," hereafter to be described, and with the integuments of the posterior region of the foot: instead of terminating in this manner, however, a more accurate examination shows it to be suddenly inflected inwards, pursuing its course towards the centre of the foot, where, diminishing gradually in depth, it is finally lost, becoming mixed up with the "sole," near the point of the frog, thus forming a distinct and remarkable internal wall that supports the under parts of the foot, and at the same time protects, by its bold projection, the sole and the frog from an undue degree of pressure and contusion against the ground.

The parts thus formed by a continuation of the wall of the hoof beneath the foot, are called the "*bars of the foot*," and are frequently described with, and taken for, part of the "sole." The direction of this sloping floor serves to throw all superincumbent pressure outwards towards the sides of the foot, and at the same time leaves a triangular space, posteriorly, for the insertion of the frog (*fig.* 513.), which it likewise protects from injury.

Fig. 513.



Structure of the hoof of the Horse.

1, the sole; 2, section of the horny hoof; 3, upper surface of the frog; 4, 4, the horny heels; 5, Bars of the foot; 6, walls of the hoof; 7, 8, 9, 10, 11, boundaries of the vaulted space, in which the frog is lodged; 12, 12, the sensitive foot.

The wall thus constructed appears to form the basis of the mechanism of the hoof, to which all the other parts are subordinate, and, if so understood, will much facilitate our views of the nature and economy of its structure. Its inner surface is every where lined, as it were, with numerous elastic lamellæ that project internally, and arranged in parallel lines, proceeding downwards perpendicularly towards the front of the foot (*fig.* 514, 3.): these horny laminæ are, at least, five hundred in number, and afford, from the aggregate surface that they present, a very extensive superficies for the attachment of an equal number of similar processes, derived from the vascular surface that covers the coffin bone, with which they interdigitate in such a way that the pressure to which the foot is subjected, which if concentrated upon a small surface would inevitably cause the destruction of living tissues, becomes so diffused as to produce no inconvenient results.

The horny lamellæ above alluded to, when removed from the hoof, have little or no elasticity when drawn in a longitudinal direction; but when drawn transversely, they possess this quality in a very remarkable degree, more especially in resisting pressure applied in a direction outwards and downwards, to resist which, the arrangement of their fibres is, on close examination, found to be particularly adapted.

The whole horny hoof, if unravelled by maceration or long continued exposure, is found to be essentially composed of longitudinal corneous threads or hairs matted, and, as it were, strongly glued together, — a structure preeminently adapted to combine all the requirements of strength, elasticity, and toughness.

As it approaches the quarters and heels, the horny helmet encasing the foot diminishes in its thickness as well as in height, affording, by this means, a degree of pliancy, which here becomes as necessary as firmness and unyielding solidity were in the front of the organ; yet, even here, by the doubling in of the hoof towards the sole, a strong horny margin is left, which is admirably adapted to receive the principal bearing of this part of the foot, and to protect and defend the sole enclosed within its curvature.

Frog. — The triangular chasm left by the inflections of the wall towards the centre of the foot, is filled up by a very remarkable organ, named, in the language of farriery, the "frog," either from some fancied gross resemblance which it bears to that animal, or, more probably, by corruption, from the French "fourche" or "fourchette," Anglicè "fork," applied to the same structure. By Latin writers, it is generally known under a similar appellation, "furca," and by the Greeks was named "χελιδονα," from a similarity between its shape and that of a swallow.

This body, which externally has the appearance of a triangular mass of elastic horn, may not be inaptly compared to an elastic key-stone received into an elastic arch communicating in some cases, and admitting in all, the springing movements of which such an arch would be capable. Its bar, which, towards the heels, is thin and broadly spread out, possesses a considerable degree of flexibility, which is gradually lost in approaching the centre of the foot, where there is less occasion for movement.

The *base* of the frog lies between and connects together the two posterior incurvations of the hoof; it then passes over and envelopes those parts, restraining their action. The *sides* of the frog are united by applied surfaces to the upper edge of the arch formed by the sole, or more truly the bar formed by the continuation of the wall. Its *point* extends to or beyond the centre of the sole.

The frog recedes from pressure in the natural foot, by having its level within the level of the other parts of the under surface of the foot, taking a third rate or degree of bearing upon the ground: the *wall* first; the *bar* next projecting beyond it: its base also retires further from pressure than the other parts of it, and is protected by the projecting angles of the *horny* or *lower heel.*

On either side, the frog is bounded by deep longitudinal excavations or channels, named the *commissures of the frog;* the bottom or deepest part of these channels, forming the line of union of the frog with the bar, a space is thus afforded on either side of the frog, which, as an elastic body, would have been useless without it; for in vain would elasticity have been given to any part, unless sufficient room was also given for its expansion. Towards the heels, these commissures are of considerable width, and they are there arched over by horny prolongation, from the base of the frog, named the *arch of the commissure.* The other extremity of the commissure growing, by degrees, shallower, is lost in the level of the sole, before it approaches the arch of the frog.

Seen from without, the frog makes a bold projecting appearance, as though it were a solid body of horn; and the smiths, deceived by this appearance, entertain but indifferent notions of its real structure, and use their paring knives upon it much more freely than its thickness warrants; for it is in reality only an inverted arch of horn that is turned downwards and reversed in respect to the general arch formed by the sole and bar, so that its real thickness in horn is by no means so considerable as on a first view it would appear to be.

Examined from within—that is to say, when the foot has been drawn forth from the hoof—the frog presents an inverted triangular arch, so intimately connected with the bar and sole, that no one would suspect it of being a distinct or divisible part, one uniform uninterrupted surface being everywhere observable on this inside: it may, however, be exhibited as a distinct inserted part by making a horizontal section of the foot through the union of the bar with the side of the frog, when the difference of their structure and appearance, and the line of their applied surfaces become sufficiently visible and distinct. A hoof exposed to the weather will also be seen in its decay to separate at this part first, and thus readily show its distinctness from the rest of the hoof.

In a perfect, well-formed foot, undistorted by shoeing, Bracy Clark observes that "the base of the frog occupies a certain division of the general circle of the hoof, and that this division is about a sixth part of the whole circumference. By knowing this fact we are not only led to entertain more just notions of the form of the foot and the proportions of its parts, but it affords us also an easy means of forming a pretty accurate guess of what injury or diminution the foot has sustained at any period of the life of the horse without previously seeing the original state of the frog."

The wings or lateral processes above described, as extending from the base of the frog, not only enclose the posterior ends or doublings in of the hoof, but the same horn is continued around the whole upper edge or margin of the roof, forming a broad convex band, whose upper edge, projecting higher than the hoof itself, receives and covers over the terminating edge of the skin, where it meets the hoof, and thus protects this part from external injuries, to which it would otherwise be liable. Posteriorly it is of considerable breadth, and firmly connects the frog with the upper part of the slope of the horny heels, over which it likewise expands. This structure, first described by Bracy Clark, received from him the denomination of the " coronary frog-band."

In the centre of the frog, as viewed from the sole, is a considerable cavity, the edges of which are furnished with rising lips or prominent margins of the horn; this hollow is termed the *cleft of the frog*, and extends to a considerable depth. This cavity appears to serve the following useful purposes *: — 1st. It is a safeguard from rupture between the two halves or divisions into which the foot is almost separated. 2dly. By closing when pressure comes direct upon the underside of the foot, it prevents too much condensation of the horn at this part, and consequent pressure and a too solid resistance upon the soft parts beneath. 3dly. When the foot bears partially upon the ground, as by one side only, which will happen occasionally where the surface is irregular, it can extend along with that side of the foot without rupturing, by the greater liberty it thus affords to the part, while at the same time the strength of its margin secures it from laceration. 4thly. On loose soils this indent or cavity will doubtless assist in giving the foot a firmer hold by the irregularity it offers to the surface.

It is, however, upon the inner aspect of the hoof that the most remarkable part of this structure is to be observed, for when examined internally it is found that the external cleft is only the hollow base of a cone of stout horn of considerable size, which passes from it directly into the substance of the sensitive frog, and which, though completely imbedded in the soft parts, is nearly or quite as hard and tough as is the horn of the exterior of the frog which is exposed to the air. This remarkable provision seems to serve the purpose of uniting more firmly the two halves of which the foot of the solipeds at this part really consists, there being here an evident tendency, in the tegumentary defences of the horse's foot, towards that division which in the ruminating quadrupeds is completely carried out. This important cone of horn Bracy Clark named the *frogstay* or *bolt*, observing that, like an inserted tooth, it more firmly holds the horny to the sensitive frog, for while the sensitive frog falls into the inverted arch of the horny frog, and is thus held most firmly in its place, this part, entering in the opposite direction into the sensitive frog, serves reciprocally to confirm and fix these parts together, and preserve them from external injury and dislocation. An excellent view of this piece of anatomy is obtained by making a perpendicular section of the foot extending through the " heels and surrounding elastic matter."

* Bracy Clark, op. cit.

The Sole. — This is an irregular plate of horn, which serves to close up the space or great inferior opening described by the lower circumference of the wall, and makes the third member or part of the hoof. It is usually of an arched form, more or less flattened, its concavity being turned to the ground, so that its centre, which is the thinnest part, is by this means removed from the degree of external pressure which the sides or bottom part of the arch have to support.

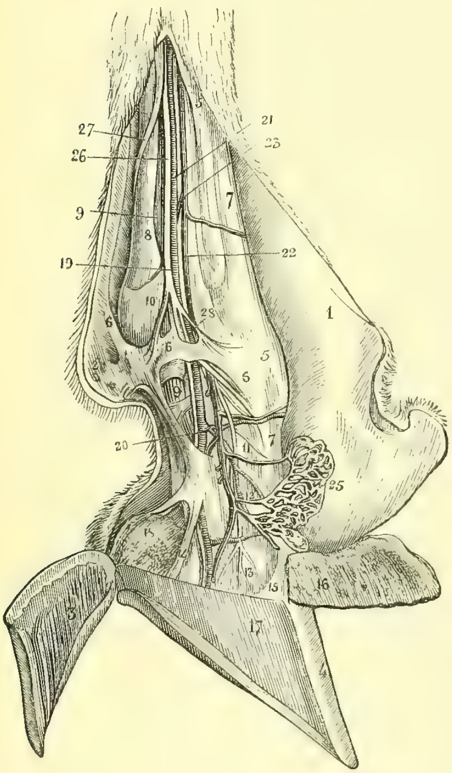
Nature has secured herself, by the arrangement of this part, in two ways from the resistance which an arch of common properties would create on becoming condensed under pressure, and forcibly resisting the load brought upon it, which would have been subversive of the leading principles of the mechanism of the hoof. In the first place the sole being cleft to its centre or beyond it by the large triangular opening formed at its posterior part, which, destroying the resistance of the arch, serves to receive the ends also of the wall of the hoof first, and is then closed and filled up by the inverted arch of the frog; so that the ends of the hoof are thus tied in and secured from being forced asunder by the pressure from within, being thus wedged in between the frog and the sole, serving in their places the other offices already noticed, while the sole, being thus broken, has a diminished resistance in the centre.

Again: the lower circumference of the arch of the sole is everywhere found abutting against the sides of the wall, which are rendered sufficiently flexible outwards to yield to the weight when pressed against by the descent and flattening of the sole, so that every provision for the elasticity of the foot is thus fully secured.

The horse's hoof is therefore fully provided with the means of preserving its form; but this power is unfortunately grievously interfered with by the process of shoeing; and it is in this country at least a very rare occurrence to obtain an opportunity of examining a foot in its full-grown natural condition.

From the above description of the foot of the horse it will be seen that, although when viewed in front it appears to be solid and single, the terms *Solidungula* and *Solipes* convey but a very imperfect notion of the real nature of this kind of hoof; for though the front be solid the posterior parts possess the greatest degree of elasticity, short of being actually cloven, that can be imagined from the sole being open to its centre and filled up with the frog. In such a foot as the term Solidungula would imply, or a continuous circle of horn, no animal could long stand, much less move, without great fatigue and pain from compression, which would soon become destructive. If it were necessary to employ any single epithet to express the real nature of this kind of locomotive apparatus, Bracy Clark suggests that the term *Semifissipes*, or half-cloven foot, would be less objectionable, though also not exactly true, on account of the presence of the frog, which, added to the entire hoof in front, seems to afford the most essential character of this kind of foot.

Fig. 514.



Dissection of the superficial Parts of the Horse's Foot.

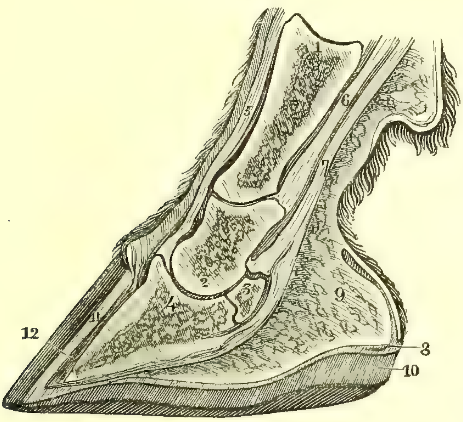
1, General integument; 2, fatty mass, forming a cushion behind the great pastern joint; 3, wall of the hoof turned back, showing the vertically lamellated horny processes projecting from its inner surface; 4, section of the wall of the hoof; 5, articulation between the cannon bone and the great pastern; 6, 6, 6, aponeurotic tissues; 7, 7, tendon of the extensor longus digiti pedis. 8, 9, 10, the flexor tendons of the foot; 11, 12, 13, 14, 15, expansions of the great anterior cartilage of the foot; 16, the coronary frog-band raised from the hoof; 17, the vascular or sensitive hoof; 18, elastic cushion of the heels; 19, 20, 21, arteria plantaris; 22, 23, plantar veins; 25, part of the coronary venous plexus raised from its position; 26, 27, 28, plantar nerves.

Cartilages of the Foot. — On removing the hoof there are seen immediately beneath it two large elastic cartilages ranging to a great extent along both sides of the foot. Their figure is almost too irregular for comparison; but, when seen on a lateral view of the foot, their shape may be said to resemble that of a lozenge or of a pretty fully expanded fan, fixed by its centre, which is very much thicker and more solid than the other parts, in a deep horizontal cavity or channel in the coffin bone provided for its reception; from this central point of insertion the anterior portion of it, passing forward, nearly meets the cartilage of the opposite side in front of the foot, the great extensor tendon of the foot only separating them, with which they are likewise connected, and make a common surface. On its inside this extremity of the cartilage takes a strong adherence to the condyles of the coronary bone, and so closely surrounds the joint betwixt the latter and the coffin bone that the articulation appears to be without any capsular ligament at this part. The posterior portion of the cartilage, ranging more largely and becoming thinner as it expands itself backwards, growing at the same time more elastic in its texture, is gradually and inseparably mixed up towards the hinder part of the foot with the skin and the ligamentary elastic tissues that form the "upper heels," and constitute the principal materials for elasticity in these parts. Spreading also in an upward direction to a considerable height above the hoof, it terminates by a rounded, thin, and irregular edge, which is inflected inwards over the soft interior of the foot, to which it forms a kind of roofing and defence.

Next, this widely distributed cartilage may be observed passing downwards, and surrounding on every side the rough and knotty extremities of the heels of the coffin bone, entering and filling up its sinuosities, and taking strong adherence to these processes; it then extends itself horizontally inwards, passing over the horny sole and bar, and, meeting the side of the sensitive frog, intimately unites with it, forming one inseparable mass, and together filling up the whole internal area described by the sides of the coffin bone. The upright or lateral portion of the cartilage forms, with this horizontal process inwards, a right angle, thus making together a hollow space or receptacle at the back of the coffin bone, that contains the spongy elastic stuffing of the heels, together with the tendons, trunks of bloodvessels, nerves &c., passing through this part to the sole of the foot. The upper surface of the horizontal process of cartilage is full of scabrous elevations and depressions that defy dissection, among which there exists a quantity of a gelatino-ligamentous material. Beneath, or to the under surface of this horizontal layer of cartilage, the sensitive sole and bar are adherent; and, in approaching the frog, or centre of the foot, it loses its cartilaginous nature, and becomes coriaceous, or rather ligamento-coriaceous, in texture, agreeing in this with the internal frog.

The horizontal portion or process of the cartilage, named by veterinary writers the "*stratiform process*," is of greater thickness and substance than the other parts; it is also of a coarser grain and more elastic nature; both portions together communicate the general boundary and form to the lateral, the posterior, and inferior parts of the foot; and when the bars or frog are thrust upwards by pressure from without, they are then acting against this same horizontal flooring, formed by the cartilage and the frog, and met by the depression of the bones of the foot forced down from the weight of the animal; the whole can then dilate exteriorly along with the posterior and more elastic parts of the hoof.

Fig. 515.



Longitudinal Section of the Foot of the Horse.

1, Great pastern bone; 2, lesser pastern or coronary bone; 3, sesamoid bone implanted in the flexor tendon of the last phalanx; 4, coffin bone; 5, tendon of extensor digiti; 6, tendon of flexor sublimus; 7, tendon of flexor profundus; 8, section of the posterior expansion of the great cartilage; 9, soft cushion of the heel; 10, section of horny hoof; 11, sensitive hoof; 12, anterior section of the cartilage spreading over the coffin bone.

The objects attained by the introduction of this admirable structure into the foot of the soliped are various, and have been well pointed out by Bracy Clark, in his excellent treatise, to which we must refer the reader for many practical applications connected with the veterinary art, that would be foreign to the objects of the present article. First, seeing that the resistance of a solid unyielding support would have been inadmissible, the pedal cartilages are employed as a substitute for bone, and made to occupy a very large share in the composition of the hinder part of the foot; for it will be remarked, the coffin bone, except by its extremity, does not extend beyond the middle of the hoof (*fig.* 515.), the posterior shape of the foot being almost wholly communicated by the cartilage, which, passing nearly around the whole coronary circle, serves to support and convey the skin to its lodgment in the coronary concavity of the hoof. Secondly, it serves to equalise the pressure every where over the internal surface of the hoof when under the pressure of the weight from within, during the descent of the bones of the foot, and, what is singular, the hoof itself is the most solid material of these hind parts of the foot.

A more important office still remains to be explained, namely, that of supplying the coffin bone with a considerable share of its capability of motion in the interior of the hoof; for it is to be remarked that, as the coffin bone is obliged to describe in its descent a small portion or segment of a circle, at its back part, round its centre of motion, or rather its more fixed part (for there is none of it wholly fixed), towards the front of the foot; so this could not so well have been accomplished had the bone itself been fixed at its upper part to the processes in front of the hoof, these being too inconsiderable to afford, in that part of the bone, the extent of motion required; but, by the intervention of an elastic cartilage between the bone and the substance of the hoof, the bone acquires greater liberty for action, and movement of its upper parts.

The cartilages of the foot, in old horses, not unfrequently become partially ossified, in which condition they are known to farriers by the name of ring-bones.

Soft Parts of the Foot. — On removing the hoof, and its horny appendages situated beneath the sole of the foot, the whole subjacent surface is found to consist of a thick, villous looking, and highly vascular membrane, moulded exactly to its inner surface, to which the name of *sensitive foot* is generally applied; or, according to the structures beneath which it is situated, it is sometimes divided into sensitive hoof, sensitive frog, &c. This structure is, indeed, the matrix from which the entire corneous hoof derives its origin, and is essentially similar, in its texture and functions, to the soft core upon which the hollow horns of many ruminants and the vascular secreting surfaces upon which the nails and claws of unguiculate quadrupeds are formed. Externally it presents, upon the anterior surface of the foot, the broad vascular laminæ which interdigitate with the horny plates, projecting from the interior of the hoof, as described above, so as to amplify, to a very considerable amount, the extent of surface whereby the contact between the sensitive foot and the wall is effected.

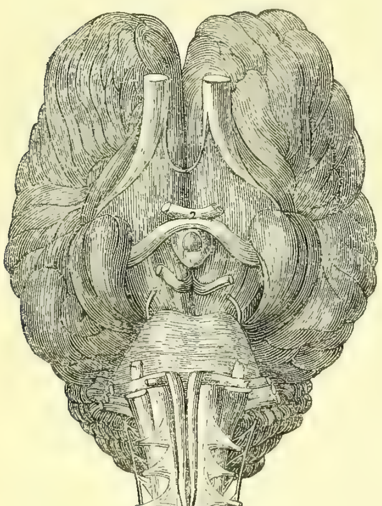
This entire surface is richly supplied with nerves and bloodvessels, the latter of which open into capacious plexuses, that surmount the coronary margin of the hoof (*fig.* 514.), and, when injected, present a very beautiful appearance.

Nervous System and Organs of the Senses. — The general arrangement of the nervous system and structure of the organs of sensation offer in the class before us no peculiarities of sufficient physiological importance to require a detailed description: we append, however, figures representing the cerebral convolutions and the base of the encephalon of the horse for comparison with similar figures given in other articles.

Fig. 516.

Brain of the Horse, showing the Convolutions.

Fig. 517.



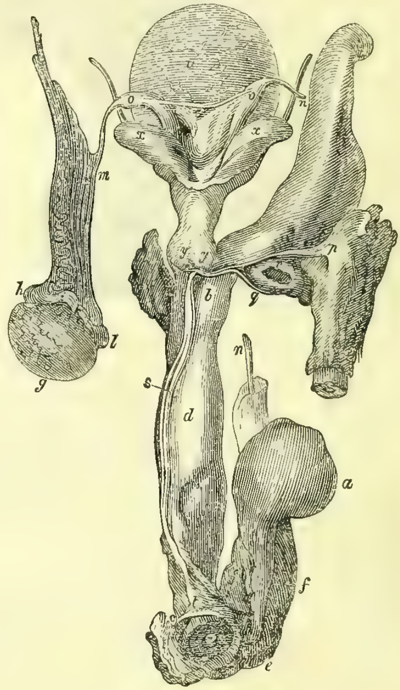
Base of the Brain of the Horse, showing the origin of the Cerebral Nerves.

Organs of Generation. *Male Generative Organs.* — The external organs of generation in the male solipeds are remarkable for their great development, and in nearly equal proportion are these animals conspicuous for their vigorous and fruitful generative powers, which, however, are only called into full activity at a certain season of the year, namely, in this climate, from the beginning of April till the latter end of June, during which period he will efficiently serve fifteen or eighteen mares.

The *scrotum* is suspended between the thighs at a distance of about nine inches beneath the anus, whence it is prolonged forwards, to terminate in the prepuce (*fig.* 518. *a, f, e*).

The *penis* (*fig.* 518. *b, c, d*) is full a foot in length even in its undistended state, measuring from the bifurcation of the corpora cavernosa (*b*) to the extremity of the glans (*c*), which latter organ is itself nearly half a foot in length, and four inches in circumference; its shape is cylindrical, and it is covered with a soft and smooth skin.

Fig. 518.



Organs of generation of the Stallion.
(After Daubenton.)

a, the scrotum; *b, c, d*, the penis; *e*, the prepuce; *f, f*, the rudimentary mammæ; *g*, the left testicle removed from the scrotum; *h*, the epididymus; *i, k*, the upper margin of the testis; *l, m*, vas deferens; *n*, vas deferens from the opposite side; *o, o*, enlargements of the vas deferens before their termination; *p, q*, tendinous bands derived from the root of the tail, these, after embracing the end of the rectum, *r*, run along the penis, *s*, as far as the prepuce, *t*, where they terminate; *v*, the urinary bladder; *x, x*, vesiculæ seminales; *y, y*, Cowper's glands.

The *testicles* (one of which only (*g*) is represented in the figure) are of an ovoid flattened form, each being about three inches long by two inches broad, and one inch and a half thick: the *epididymus* (*h*) issues from its anterior part, and is composed of large tubes of a yellowish colour, bound up together in numerous small bundles. Arrived at the posterior extremity of the testes, the epididymus folds back upon itself, to constitute the vas deferens; which, at its commencement, is very tortuous, and forms a protuberance of considerable size (*l*). The *vasa deferentia* (*l*, *m*, *n*) are upwards of fourteen inches in length, and, during the greater part of their course, about two lines in diameter; but towards their termination they become, for a length of about seven inches, much dilated, here measuring upwards of fifteen lines in circumference (*o o*). The caliber of the internal canal does not, however, expand in proportion to the dilatation of the exterior of the duct.

Female Organs of Generation.— The generative organs in the female solipeds offer no variations of structure from the usual type common to placental quadrupeds. The *clitoris* (*fig.* 519. *a*) is of great size, and is lodged in a cavity appropriated to its reception, situated immediately above the inferior (*i. e.* anterior) commissure of the labia pudendi; its glans is enclosed in an ample prepuce, above which may be observed an orifice leading into a cavity big enough to lodge a small bean. The canal of the *vagina* is about a foot in length, and in its capacity corresponds with the ample dimensions of the penis of the other sex.

Immediately behind the orifice of the urethra, the mucous membrane of the vagina forms a broad fold, which is directed forwards and lies immediately over the urethral opening: the length of this fold in the adult mare is about eight inches, and, near its middle, it is upwards of an inch in breadth.

The *urinary bladder* is small in comparison with the size of the animal; its shape is nearly round; and its circumference, when moderately distended, about a foot and a half. The urethra is remarkably short and capacious, the circumference of its canal being about three inches, while its length is only about an inch and a quarter.

The *orifice of the uterus* (*i*) projects to the distance of about half an inch into the upper end of the vagina, and is of a rounded shape, encircled by a thick margin. The womb is made up of the body and two cornua, which latter, in the unimpregnated state, measure about seven inches in length.

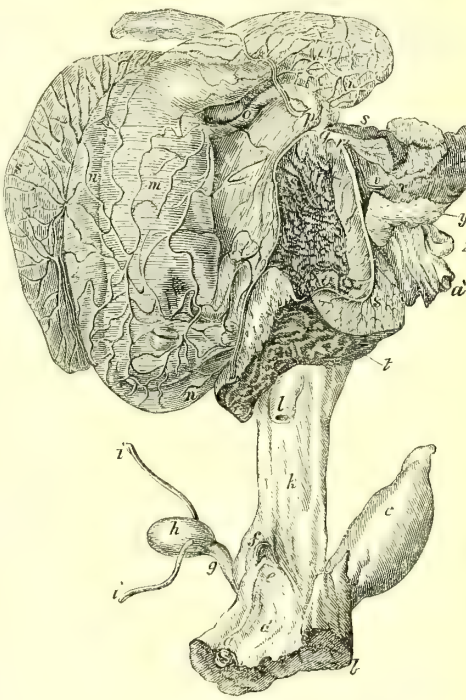
The *ovaria* and *fallopian tubes* present nothing remarkable in their structure or arrangement.

Gravid Uterus.— The anatomy of the contents of the gravid uterus, and the arrangement of the membranes that enclose the fœtus offer some peculiarities worthy of notice.

The fœtus in utero in the solipeds, is enveloped in the usual uterine membranes,— the amnion, the chorion, and the allantoid; but the disposition of these envelopes differs remarkably from what exists in the ruminants, and many other quadrupeds.

The *urachus* (*fig.* 520. *a*) issues from the umbilicus in company with the umbilical arteries and vein (*b*), and, in the ovum represented in the figure, was found at some distance from the umbilical opening to measure about five inches in circumference, beyond which point its diameter gradually diminishes, till it reaches the point at which the amnion spreads out on all sides to envelope the fœtus, where it terminates by the orifice *e*, and is prolonged to form the allantoid, which encompasses the rest of the cord. On the arrival of the allantoid at the extremity of the cord, it extends itself upon the chorion to which it becomes adherent, lining its internal surface in such a manner, that the two seem to form but a single membrane, the inner surface of which is formed by the allantoid (*g*), its exterior by the chorion (*h*).

Fig. 519.



Organs of generation and gravid uterus of the mare. Vagina laid open. (*After Daubenton.*)

a, the clitoris; *b*, anus; *c*, rectum; *d*, posterior surface of the vagina; *e*, the orifice of the urethra; *f*, membrane which covers the urethral opening; *g*, the canal of the urethra; *h*, the bladder; *i*, *i*, the ureters; *k*. continuation of the vagina; *l*, orifice of the womb; *m*, fœtus as seen through the transparent amnion, *n*; *o*, portion of the umbilical cord that extends from the umbilicus of the fœtus as far as *p*, the point where the amnion spreads out; *q*, portion of the umbilical cord which extends beyond the amnion to the point *r*, where the chorion and the allantoid become united; *s*, the allantoid; *t*, the chorion seen from its outer surface; *v*, a hippomanes attached by its pedicle; *x*, *y*, chorion adherent to the uterine walls by numerous rugæ; *z*, the left ovarium; *a'*, the spermatic vessels.

The size of the umbilical cord gradually enlarges as it approaches the chorion, owing to the progressive dilatation of the vessels composing it as they recede from the umbilicus.

The *allantoid* in the mare does not form a closed bag, as it does in the ruminants, but lines about half of the interior of the cavity that exists between the amnion and the chorion. To form an idea of this cavity and of the space occupied by the allantoid, it will be necessary first of all to consider the amnion as a sac, in which the fœtus is enclosed, and the allantoid and the chorion as forming another sac of larger size, by which the former is enveloped in such a manner, that an interspace is left between the two : this interspace is traversed by the second portion of the umbilical cord as it passes from the former sac towards the latter, and in this course, the cord is enveloped by the allantoid membrane, which subsequently invests all the interior of the second sac formed externally by the chorion.

Fig. 520.

Anatomy of the gravid uteris of the mare. (*After Daubenton.*)

a, the urachus emerging from the umbilical opening of the fœtus, accompanied by the umbilical vein; *b*, and by two umbilical arteries; *c*, continuation of the umbilical cord as far as the expansion of the amnion; *d*, *d*, *e*, termination of the urachus; *f*, continuation of the umbilical cord; *g*, *g*, allantois; *h*, the chorion; *i*, an hippomanes adherent to the allantoid by its pedicle; *k*, *l*, *m*, two other hippomanes of smaller size. The other letters refer to the generative organs of the fœtus (a female) shown in connection with the above parts; *o*, the rectum; *p*, the anus; *q*, the bladder of urine communicating with the urachus; *r*, *r*, the ureters; *s*, canal of the vagina; *t*, orifice of the urethra; *v*, first appearance of the membrane, which subsequently spreads over the urethral orifice; *x*, *x*, the cornua uteri; *y*, separation between their internal cavities; *z*, *z*, the ovaria.

The aperture of the urachus pours forth a glairy fluid of a reddish colour, which is received into the cavity, the boundaries of which are described above: this fluid has a urinous smell, especially when heated, and moreover contains certain solid bodies, which have been from time immemorial dignified with the name of *hippomanes*, and were by the ancients supposed to be possessed of various mysterious qualities, and magical influences.

The *Hippomanes* was considered, until a very recent period, to be a piece of flesh growing upon the forehead of the nascent foal; and it was not until Daubenton presented a memoir upon this subject to the Royal Academy of Sciences in Paris *, that its real nature was understood. The hippomanes were then found to be merely masses, of a thick substance, of variable dimensions, contained in the allantoid cavity, which, although they might occasionally during parturition after the laceration of the membranes, become adherent to the head of the fœtus, are, in reality, produced between the amnion and the allantoid membranes.

These bodies are very variable in their size, and frequently several are met with, the dimensions of which vary from the size of a pea to that of a large pear, some of the latter weighing as much as five or six ounces. They are composed of a viscid substance of an olive brown colour, and frequently have irregularly shaped cavities in their interior; but they present no traces of organization. When cut into they seem to be made up of numerous superposed layers, and externally their surface is covered with floating filaments : sometimes they are found to be attached by long pedicles to the walls of the allantoic cavity ; but, whatever their shape, they are evidently merely sedimentary deposits from the fluid in which they are immersed, and indeed may be formed at pleasure by slowly evaporating the contents of the allantoic sac. These structures are indeed by no means peculiar to the horse, but are frequently met with in other animals.

The exterior of the chorion is everywhere in contact with the uterine walls, and in shape represents exactly the interior of the cornua uteri, upon which it is moulded, the placenta occupying the greater portion of its extent.

Mammary Glands.—It was generally believed from the time of Aristotle until a very recent period, that in the male horse there were no nipples or other rudiments of the

* Mémoires de l'Académie Royale des Sciences, années 1751 and 1752.

female mammæ; except, as Aristotle expresses it, in such animals as resemble their mothers*: that is to say, in other words, that there were a few exceptional cases. Subsequent authors have stated the same concerning male solipeds in general†, although none stated in what the resemblance consisted, or where the mammæ in those furnished with them were situated; so that even Buffon asserted it as a fact, that the male solipeds had no vestiges of mammæ. Daubenton, however, having previously discovered the situation of these organs in the male ass, was led from analogy to expect their presence in the horse likewise, and soon detected them, but situated in a very unusual position, — namely, upon the prepuce of the animal. The prepuce of the stallion is found to form a kind of prominent ring around the aperture through which the penis is protruded, and it is upon this circular protuberance, close to the sides of the scrotum, that the mammæ are situated. These organs are two in number (*fig.* 518. *ff*), situated at a distance of about half an inch from each other, and are easily distinguishable from the circumstance of the skin being raised into a papilla around each nipple, in the centre of which there is a shallow depression. It would seem, however, that in old horses the presence of these rudimentary mammæ becomes less apparent.

In the mare, the mammary glands are situated between the thighs at a distance of about nine inches in front of the vulva. The nipples are only two in number, one on each side of the mesial line, and their distance from each other is not more than an inch and a half. As in the goat and many herbivorous quadrupeds, all the lactiferous ducts form, in the base of each gland just above the root of the nipple, a large hollow cavity, which is divided by an internal septum into two chambers, one situated in front, and the other behind; from each chamber a separate duct is derived, which passes along the nipple as far as its extremity, where it terminates. The orifices of these canals are situated, one behind, the other about a line, apart. It is owing to the presence of the reservoirs thus formed by the cavities of the mammary glands, that the lacteal secretion is permitted to accumulate in considerable quantities, until required for the nourishment of the young, or removed by human agency for the purpose of procuring the milk, which is frequently employed as an article of diet.

SPINAL ACCESSORY NERVE (part of the sixth pair of the older anatomists; part of the eighth pair of Willis; *nervus accessorius ad par vagum; nervus accessorius Willisii*; the eleventh pair of Soemmering; the *beinerve* of the German anatomists). This nerve is attached to, or, as it is more commonly expressed, arises from, the lateral surface of the cervical portion of the spinal chord close to the posterior roots of the spinal nerves; and it lies between the posterior roots of the spinal nerves and the ligamentum denticulatum. On entering the cranium by the foramen magnum, it continues to receive additional roots or filaments of origin from the medulla oblongata. It commences by a very slender filament, most generally opposite the fifth or sixth posterior roots of the spinal nerves, and in its passage upwards to the interior of the cranium, its bulk is gradually increased by additional filaments of origin from the lateral surface of the spinal chord and from the medulla oblongata. The filaments arising from the spinal chord pass upwards and a little forward to join the trunk of the nerve, so that it lies a little nearer to the ligamentum denticulatum than the attachments of the filaments forming it. After it enters the cranium by the foramen magnum, it runs forward, outward, and upward, places itself in close apposition to the posterior surface of the par vagum, and escapes from the interior of the cranium, through the foramen lacerum posterius, along with the vagus and glossopharyngeal nerves. The roots of the accessory that arise from the medulla oblongata are placed in the same line with the lower roots or filaments of origin of the par vagum; and the upper roots of the former approach so closely to the lower roots of the latter, that it is frequently difficult to say with confidence where the roots of the one nerve end and those of the other begin. (*Fig.* 521, 3, 5.)

Previous to the time of Willis, anatomists considered this nerve as constituting a part of the vagus, and to him is due the credit of first pointing out clearly the grounds on which its separation from the vagus rests. Very great discrepancy exists in the description of the origin of this nerve given by the best anatomists. This is explained, not only by the fact first pointed out particularly by Scarpa*, that its filaments of origin are attached over different extents of the spinal chord in different individuals, and sometimes to a greater extent on one side than on the other in the same individual, but also by its lower roots or filaments of origin being so slender that they sometimes cannot be accurately traced by the naked eye. Willis himself describes it as commencing by a very slender beginning near the sixth or seventh cervical nerve.† Scarpa ascertained that its

* Abhandlung über den zum achten Paare der Gehirnerven hinlaufenden Beinerven. In den Abhandlung der röm. K. K. Josephinischen Med. Chir. Academie, Band i. Wien, 1787.

† Cerebri Anatome, &c., Caput xxviii. p. 294. Amstelodami, 1666.

lowest root may be attached to the spinal chord opposite the fourth, fifth, sixth, or seventh cervical nerve, but more frequently between the fifth and sixth; and that when its roots are extended over a more limited portion of the spinal chord, this is compensated for by their being proportionally stronger.*

Anatomists have differed as widely in their account of the particular column or tract of the spinal chord to which the roots of the spinal accessory are attached, as they have done regarding the extent of the spinal chord over which these roots stretch. This is a point in the anatomy of the nerve which has assumed greater importance since the discovery by Sir Charles Bell, of the separate functions of the anterior and posterior roots of the spinal nerves, and is of much more interest to the modern, than it was to the older anatomists. The filaments of origin or roots of this nerve that come from the spinal chord are attached to the chord near the posterior lateral groove separating its posterior and middle columns, and close upon the posterior roots of the spinal nerves, so that we can readily understand how some anatomists should describe these roots as arising from the middle column, and others describe them as springing from the posterior column.† Among the modern anatomists we find Bellingeri, who has attended particularly to the anatomy of this nerve, describing it as arising from the middle or lateral column of the spinal chord*, while Bischoff† and Bernard‡ trace its origin to the posterior column; and Bendz§ states that while nearly the whole of its roots come from the middle column, a few arise between the posterior roots of the spinal nerves and from the posterior column.‖ From my own examinations of the attachments of this nerve, I had arrived at the conclusion that it arises from the posterior part of the middle column, and that its middle and inferior roots are attached along the course of the decussating fibres of the pyramidal column, which form the posterior part of the middle column of the chord.¶ Stilling says** that the lower and middle roots of this nerve can be traced to the anterior grey substances in the chord, from which the anterior roots of the spinal nerves arise, and that, in an anatomical point of view, they must be regarded as performing the same functions as the anterior roots of the spinal nerves; while the upper roots, or those which are attached to the medulla oblongata, differ in a marked manner, in regard to their origin, from the lower and middle roots. He states that these upper roots above the first cervical nerve arise from a grey mass in the medulla oblongata, which he styles the *accessory-kernel* (accessorius-kern††), and that they resemble closely the lower filaments of origin of the par vagum. These upper roots of the accessory do not arise from the gelatinous substance from which, according to Stilling, the posterior roots of the spinal nerves spring, yet they come into closer relation with it the nearer they approach to the commencement of the roots of the vagus. The upper fibres of the accessory, though not continuous with the posterior roots of the spinal nerves, are yet, he believes, analogous to these; and this view is strengthened by their presenting the same connection with the roots of the hypoglossal as is found between the roots of

* Huber (De Medulla Spinali, et speciatim de Nervis ab eâ provenientibus, p. 13.) says that this nerve commences opposite the seventh cervical, but he afterwards speaks of it arising opposite the sixth. Lobstein (De Nervo Spinali ad Par Vagum Accessorio, p. 233, as reprinted in Ludwig's Script. Neurol. Min. Selec. tom. ii. Lipsiæ, 1792) describes it as arising under the sixth pair of cervical nerves by a slender beginning. Bellingeri (De Medulla Spinali, Nervisque ex eâ prodeuntibus, p. 74, 1823) places its origin opposite the seventh cervical nerve. Cruveilhier (Anatomie Déscriptive, tom. iv. p. 899, 1835) says that its origin seldom passes below the level of the fifth pair of cervical nerves, but it may arise opposite the sixth and even the seventh pair. Bendz (De Connexu inter Nervum Vagum et Accessorium Willisii, p. 22, 1836) describes its lowest root as arising from the spinal chord in the region of the fifth or sixth cervical nerves, and rarely as low as the posterior root of the seventh cervical. Valentin (Soemmering vom Baue des menschlichen Körpers. Hirn und Nervenlehre, S. 513, 1841) states that its most frequent origin is opposite the sixth, or between the sixth and seventh cervical nerves; sometimes it arises opposite the fourth or fifth, or it may extend as far as the seventh, and in rare cases as far as the first dorsal. Krause (Handbuch der menchlichen Anatomie, Erster Band, S. 1066: Hannover, 1842) says that it usually arises opposite the upper part of the roots of the seventh cervical, seldom higher. Bernard (Archives Génerales de Médecine, 4ième sérіe, tom. iv. p. 410, 1844) describes it as arising by a series of bifid or trifid nervous filaments, which extend, in man, from the origin of the pneumogastric to a point opposite the fourth or fifth pair of cervical nerves.

† Rolando (Recherches Anatomiques sur la Moëlle Ablongée) and Serres (Anatomie Comparée du Cerveau, tom. i.) have stated that the lower fibres of this nerve come from the anterior column of the spinal chord.

‖ Lobstein (De Nervo Spinali, in Ludwig's Scriptores Nevrologici Minores Selecti, tom. ii. p. 233.) also describes some of the filaments of origin of the spinal accessory as coming from the spinal chord between the fasciculi which constitute the posterior roots of the spinal nerves, and has represented these in *fig.* 1. Those who may wish to ascertain the opinions of other anatomists as to the particular column of the spinal chord into which this nerve is implanted, and the extent of its attachment to the cervical portion of the spinal chord, may consult the monographs of Bischoff and Bendz quoted above, and especially that of the former of these authors.

¶ On some points in the anatomy of the medulla oblongata, in Edinburgh Medical and Surgical Journal for 1841.

** Ueber die Textur und Function der Medulla Oblongata, pp. 55. 57. Erlangen, 1843.

†† He describes the position and structure of this accessorius-kern at p. 23. of the work quoted.

the posterior and anterior spinal nerves at their origin.

The spinal accessory in its course within the spinal canal frequently forms communications with the posterior root of the first cervical, and much more seldom with the posterior root of the second cervical nerve.* When these communicating filaments come from the second cervical, they are generally few in number. This communication between the spinal accessory and the posterior root of the first cervical is, according to Lobstein, more frequently present than absent.† When the posterior root of the first cervical joins itself, either in whole or in part, to the spinal accessory, a branch of equal size generally leaves the accessory, either at the point where it is joined by the posterior root of the first cervical, as figured and described by Asch ‡, or a little above this junction, as figured by Huber §, and described by Bellingeri.|| This branch, after leaving the accessory, proceeds outwards, approaches the anterior root of the first cervical, and takes the place of the posterior root of that nerve.¶ When the posterior root comes from the accessory, it generally presents a ganglion in the usual position. Sometimes, however, though rarely, this ganglion is found on the accessory where the posterior root of the first cervical leaves it to join itself to the anterior root. This ganglion was first pointed out by Huber; its existence has been denied by Lobstein, Asch, Haller, and Scarpa, and it has again been described by Bellingeri. I have seen this ganglion twice, and it was present on one side only. It becomes an interesting question in a physiological point of view to know, whether or not the whole of the filaments of the posterior roots of the spinal nerves which join themselves to the accessory, again leave it to form the posterior root of the first cervical. Bellingeri answers this question in the affirmative. "The filaments," he says, "coming from the posterior roots to the accessory are not intermixed, but only approximated, so that they can be separated by slight traction."**

* Scarpa states (opus cit. p. 395.) that in a great number of bodies he examined with a special reference to this point, he found a communication between the accessory and the posterior root of the second cervical only in two instances.

† Circa harum radicularum, quæ pro radicibus posticis primi paris habenter, communicationem illud notamus, quod sæpius accessorium subire, quam eundem intactum relinquere observenter. Opus cit. p. 223.

|| Opus cit. p. 80. Monro *secundus* has also given a representation of this communication between the accessory and posterior root of the first cervical. Observations on the Structure and Functions of the Nervous System, tab. x. fig. 2. 1783.

¶ Bischoff states (opus cit. pp. 34. 82.) that in none of the numerous instances in which he dissected the accessory in the lower animals, did he ever observe any filaments of the posterior roots of the spinal nerves join themselves to it.

** Opus cit. p. 81.

And in another place he says, "I believe that the filaments from the posterior roots, which join the accessory, leave it again to proceed to the posterior root of the first cervical."* From this he concludes that the accessory contains no sensiferous filaments. Müller, on the other hand, has adduced some unusual anatomical arrangements in this nerve, which may be regarded as favouring the opinion that it contains sensiferous filaments independant of those which it may receive from the posterior roots of the spinal nerves. He mentions an instance†, which he elsewhere ‡ describes at considerable length, where the posterior root of the first cervical nerve on the right side was not present, and where its place was supplied by two bundles of filaments from the superior part of the spinal accessory. The upper of these bundles, at least, came from the medulla oblongata. Upon the posterior root of the first cervical thus constituted, a ganglion was formed while it was still within the *theca vertebralis*. The upper fibres of the posterior root of the second cervical of this side joined themselves to the accessory, but no nervous filaments were attached to the spinal chord in the usual position of the posterior root of the first cervical. On the left side, the posterior root of the first cervical presented its usual appearance, and was connected to the spinal accessory by some filaments of communication. The filaments of the accessory arising from the medulla oblongata did not, as on the right side, divide themselves into two parts, one of these becoming the substitute of the posterior root of the first cervical: but the whole ran upwards into the accessory nerve.|| Müller also states that Hyrtl has often seen a ganglion upon the accessory nerve opposite the entrance of the vertebral artery into the interior of the cranium; and that Remak showed him an instance of a ganglion upon the spinal accessory at its passage through the foramen lacerum. "I do not, however, affirm," Müller remarks in reasoning from these cases, "that the spinal accessory always contains originally sensiferous filaments, but leave it doubtful." "But in the case," he continues, "where the nervus accessorius forms an intimate connection with the posterior root of the first cervical, or any other nerve, we may suppose an interchange; and this, in the same degree, will render probable the idea of Monro,

‡ Idem opus, 1837, pp. 279—281.

§ Arnold (Bemerkungen über den Bau des Hirns und Rückenmarks, &c., S. 181—183; Zürich, 1838) has published remarks upon this anomalous instance in the origin of the posterior root of the first cervical from the accessory, the object of which is to endeavour to show that Müller had misinterpreted the facts observed. Among other things urged with this view, is the circumstance that the posterior root of the first cervical does not arise usually in the same line with the posterior roots of the other spinal nerves, but somewhat anterior to these. We cannot, however, believe that so experienced and accurate an anatomist as Müller is, could fall into any such mistake as is here insinuated.

that the communication of the spinal accessory with the posterior root of the first, or with any other spinal nerve, will be an equivalent to it for a posterior root." We have already seen that Stilling concludes, on anatomical grounds, that those filaments of the accessory that come from the medulla oblongata contain centripetal filaments.*

The spinal accessory passes through the foramen lacerum posterius in a canal formed by the dura mater, common to it and the vagus, but they are occasionally separated from each other as they enter this canal by a bridle of arachnoid, or of the dura mater. Soemmering has pointed out that the accessory does not perforate the dura mater like the other nerves, but is, as it were, insensibly surrounded by this membrane.†

One or two filaments generally pass between the accessory and the superior ganglion or *ganglion jugulare* of the vagus, as they lie in the foramen lacerum posterius. Hein states that he has more than once distinctly observed, as also Krause has remarked, the superior five, or even six filaments of the root of the accessory approximate very closely to the ganglion jugulare of the vagus, and partly enter into its formation, so that a junction between the vagus and accessory had already taken place in this ganglion, before the filaments of the accessory had been fully collected to form together the trunk of this nerve.‡

As the spinal accessory is passing through the foramen lacerum, it is in close proximity to the posterior surface of the par vagum, and it there divides into its two branches — its *internal* and *external* branches.

The former, or the *internal*, is composed of the filaments forming the upper roots of the nerve (*fig.* 521, 11.), and entirely, or almost entirely, of those coming from the medulla oblongata; and it joins itself to the vagus immediately below the ganglion jugulare of that nerve. The passage of the accessory through the foramen lacerum posterius, its division into two branches, and the distribution of the internal branch as far as it is known, have been already described in the art. PAR VAGUM, vol. iii. pp. 883. and 890, and need not be repeated here.

The *external* branch, composed of those fibres which arise from the spinal chord (*fig.* 521, 12.), proceeds downwards, outwards, and backwards behind the internal jugular vein, in front of the occipital artery, and behind the posterior belly of the digastric and stylo-hyoid muscle, and reaches the inner surface of the sterno-cleido-mastoid muscle at the lower part of its upper third. In continuing its course downwards and outwards, it here generally perforates the sterno-cleido-mastoid; at other times it is only closely connected to it by cellular tissue; but in both cases it gives branches to this muscle. In this part of its course it is strengthened and anastomoses with twigs of the third and second cervical nerves. Continuing its progress downwards and backwards it anastomoses with twigs of the fourth and fifth cervical nerves, and throws itself into the inner surface of the trapezius muscle, among whose fibres it is ultimately lost.

Comparative anatomy of the spinal accessory. — The origin and distribution of this nerve in the mammalia does not essentially differ from what is found in the human species.* Willis states that this nerve is not only present in the mammalia, but also in birds and fishes †; but the existence of it in the two latter divisions of the vertebrata has been subsequently denied by many excellent anatomists. "If an animal," says Mr. Shaw, "does not perform part of the act of respiration by muscles which run from the skull to the chest, no spinal accessory is found. The truth of this observation may be shown by the dissection of any of the larger birds, but the most extraordinary proof is to be found in the neck of the camel. The constitution of the neck of this animal is like that of birds; there being a succession of short muscles along the side of the neck, and attached to the vertebræ, but no long muscle passing from the jaw to the sternum to assist in breathing, as in other quadrupeds." ‡ It appears, however, that in the camel this nerve is present, but it is smaller and differently distributed from what it is in the horse.§ Serres found it in three of the larger birds, Weber in some fishes, and Bischoff has given descriptions and representations of it in several birds, reptiles, and fishes. In these animals the upper part only of this nerve seems to be present, for it does not stretch downwards along the spinal chord to the same extent in them as in the mammalia. The whole of this nerve, in these animals, throws itself into the vagus, while a branch leaves the vagus after it has escaped from the cranium, and taking the place of the external branch of the accessory is distributed to the muscles of the neck in birds and in reptiles, and to the muscles which move the pectoral fin in fishes.|| In the chimpanzee, the spinal accessory, after passing through the foramen lacerum, divides into two branches. The internal runs towards the larynx, into which it penetrates above the os-hyoid. It is placed between the superior laryngeal nerve and stylo-hyoid ligament, and passes behind the internal carotid artery to the superior hyoi-

* Stilling further states (p. 59) that in an anatomical point of view we may regard the upper roots of the accessory forming the *internal branch* of that nerve as being composed of centripetal and centrifugal filaments, exactly like the vagus.

Physiology of the accessory.— The peculiar origin and course of this nerve, and particularly its intimate connection with the par vagum, have formed the basis of most of the speculations on its functions since the time of Willis. It was maintained by Willis that this nerve, from its connection with the par vagum, regulates those involuntary movements of the neck and arm caused by the emotions and passions.* Lobstein likewise believed that the spinal accessory joins the vagus for the purpose of connecting itself with the involuntary functions, and he supposed that its paralysis might also affect the movements of the pharynx and larynx.† Others have maintained that it is a nerve of involuntary motion from the particular portion of the spinal chord in which it is implanted. It is, as is well known, one of Sir Charles Bell's respiratory nerves, arising as he supposed from a particular tract in the spinal chord to which he gave the name of respiratory tract, and is therefore, according to this view, a nerve of involuntary motion. Bellingeri believes that the lateral tract of the spinal chord, from which the accessory arises, presides over the instinctive and sympathetic movements, and that it is consequently a nerve of involuntary motion.‡ Arnold §, Scarpa ||, Bischoff ¶, Valentin **, and Longet ††, have maintained that the accessory stands in the same relation to the vagus as the anterior roots of the spinal nerves do to the posterior roots.‡‡ According to this last view, the vagus does not originally possess any motor filaments, but derives them from the spinal accessory. The two first of these authors came to this conclusion on anatomical grounds alone; the three latter, from experiments upon these nerves in living animals, as well as from their anatomy. Bernard has arrived at the conclusion that it is entirely a motor nerve, and that it enables the larynx and pharynx, and muscles of the neck in which it is distributed, to partake in the production of the phenomena of phonation, but that it does not assist in any of the true respiratory movements.§§ Dr. Todd and Mr. Bowman || ||, on the other hand, believe that the internal branch of the accessory is composed of *afferent* nerves, and that the mode of implantation of this nerve in the central organs of the nervous system serves to bring the sentient surface of the lungs and air-passages into immediate relations with the roots of all those nerves which animate the great muscles of respiration, the phrenic, the external thoracic, the cervical plexus, and the motor fibres of the spinal accessory and vagus nerves.

All experimenters agree that the external

branch of the spinal accessory is a motor nerve. We found that when it was embraced firmly within the forceps, or tied tightly soon after it had emerged from the foramen lacerum, the animal gave indications of suffering * ; but an experiment of this kind does not enable us to decide whether these sensiferous filaments were originally contained in the accessory, or were derived from the neighbouring nerves. Mr. Shaw has detailed an experiment to show that the movements which it imparts to the sterno-mastoid, and to the trapezius are not voluntary, but respiratory.† In our experiments, and in those subsequently performed by Bernard, these muscles acted in unison with the muscles of respiration after the spinal accessory nerves had been divided.

While all experimenters agree that the external branch of the accessory is chiefly if not entirely composed of motor filaments, they have arrived at discrepant conclusions regarding the functions of the internal branch. Volkmann ‡, Van Kempen §, and Stilling ||, observed no movements of the muscles in which the internal branch of the accessory is distributed, on irritating the roots of this nerve within the cranium; while in those of Bischoff, my own, those of Valentin ¶, Longet **, Hein ††, Morganti ‡‡, and Bernard §§, partly consisting of irritating the roots of the nerve within the cranium after death, and partly, as in those of Bischoff, Longet, Morganti, and Bernard, by lesions of the nerve in living animals, and observing their effects upon the movements of the muscles in which it is distributed, proofs of its being a motor nerve were believed to be obtained. We think that this evidence is sufficiently strong to justify the belief that the internal branch of the accessory does contain *motor* filaments; but it is at the same time highly probable that it is partly composed of *sensiferous* and *afferent* filaments, and if so, its constitution must be similar to the vagus nerve, with which it becomes so closely incorporated. In the art. Par Vagum, sufficient proof has been adduced to satisfy us that the opinion that the spinal accessory furnishes all the motor filaments contained in the trunk of the vagus, is no longer tenable.

(*John Reid.*)

* Edinburgh Medical and Surgical Journal for January, 1838. Valentin states (opus cit. pp. 58. 62.) that he succeeded in increasing the action of the heart by irritating the trunk of the accessory; but Van Kempen (opus cit. p. 65) repeated this experiment without success.

§ Essai Experimental sur la Nature Fonctionelle du Nerf Pneumogastrique : Louvain, 1842. In giving the results of Van Kempen's experiments in the art. Par Vagum, foot-note at p. 891, vol. iii. upon the effects of irritating the roots of the vagus within the cranium, I have inadvertently written the palato-glossus muscle *instead of* the palato-pharyngeus or pharyngo-staphylin muscle, as one of the muscles seen to contract in this experiment. I may also here correct another error in the same article: at p. 900, it is stated that Longet believes that the secretion of the gastric juice is greater after section of the vagi than in the sound animal; while in fact he states that it is diminished by section of the vagi, and that this diminution in the secretion may be explained on mechanical grounds.

SPINAL NERVES (*Les Nerfs rachidiens*, Fr.; *Die Rueckenmarksnerven*, Germ.; *I Nervi Spinali*, Ital.) are thirty-one pairs, and are distributed to the neck, and the upper extremities, the trunk and lower extremities. They are divided into Cervical, Dorsal, Lumbar and Sacral: the first division comprising eight; the second, twelve; the third, five; and the fourth, six. Their general and special characters, and their apparent and absolute connexion with the spinal chord having been already described *, we shall limit the details of this article to their ultimate distribution.

Each spinal nerve, after the union of its roots, divides into an anterior and posterior branch, the former having generally a much more complicated and extensive distribution than the latter. It will be convenient therefore for the purpose of description to enter first into a consideration of the posterior branches.

The posterior branch of the first cervical or sub-occipital nerve is larger than the anterior, and passes internal to and below the vertebral artery, between the arch of the atlas and the occipital bone, to gain the triangular space between the rectus capitis posticus major, the superior and inferior oblique muscles. It is here imbedded in a considerable quantity of fat and dense cellular membrane, and having directed itself from before, backwards, and slightly from below upwards, divides into a series of branches. Two external branches are sent to the two oblique muscles: an internal ascends to the rectus capitis posticus major, and which having supplied this, terminates in the minor: another filament is directed to the anterior aspect of the complexus near to its occipital attachment: and the terminal branch descends, generally perforating the inferior obliquely, and anastomoses with the posterior branch of the second cervical nerve.

The posterior branch of the second cervical nerve emerges from between the lower border of the posterior arch of the atlas, and the lamina of the axis, and is larger than any of the posterior branches of the cervical nerves, and three or four times greater than the anterior branch of the same nerve. It appears at the lower border of the inferior oblique, and having passed a short distance horizontally inwards, winds round this muscle to the anterior aspect of the outer part of the complexus, which it perforates. It inclines outward and upwards between it and the

* Vide Nervous System, vol. iii. p. 657.

trapezius, passes through the latter, and terminates in the skin in the occipital region as the *great occipital nerve*, coursing along with the occipital artery but lying internal to it. Before becoming great occipital, it gives off at the lower border of the inferior oblique a branch to supply this muscle and a superior and inferior anastomotic branch to communicate with the first and third cervical. When passing along the anterior surface of the complexus, numerous branches are given off to this muscle, the trapezius, and splenius. Those for the last muscle are more numerous and larger than the branches, for the two others are directed to the anterior aspect of the muscle, and one or more of them perforate the complexus before reaching it.

The posterior branch of the third cervical is smaller than the second, but larger than the fourth, and situated more externally, emerging from between the transverse processes of the second and third cervical vertebra. It is directed inwards, between the opposed surfaces of the complexus and semispinalis colli towards the median line, and having reached the sides of the spinous processes of the vertebræ, divides into ascending and horizontal cutaneous branches. The *ascending branch*, after a short course, perforates the inner border of the complexus and trapezius, and becomes cutaneous. It continues its course close to the median line, as far as the region of the occiput, the inner and lower part of which it supplies on the internal side of the great occipital nerve.

The *horizontal branch* passes between the ligamentum nuchæ and the inner border of the complexus, and after having perforated the tendon of the trapezius, terminates in external small cutaneous filaments. The nerve prior to division, and at the outer border of the semispinalis colli, communicates by one or more filaments with the posterior branch of the second cervical. From the anastomosis between the communicating branches of the posterior roots of the three first cervical nerves, results an irregular plexus placed between the complexus and outer part of the semispinalis colli, and consequently nearly in a line with the transverse processes of the superior cervical vertebræ. From this *posterior cervical plexus*, numerous branches arise to supply the complexus, splenius, and semispinalis colli. The anastomosis between these posterior branches is, according to Cruveilhier, sometimes deficient.

The posterior root of the fourth cervical nerve varies much as to individual size, but is always smaller than the preceding. It passes downwards and inwards between the complexus and semispinalis colli, and having reached the side of the median line, perforates the tendons of the splenius and trapezius, and becomes cutaneous. In its course it supplies these muscles, and occasionally terminates in the splenius without going to the skin.

The posterior branches of the fifth, sixth, seventh, and eighth cervical nerves have a similar course to the fourth, but decrease in size from above downwards. The fifth and sixth usually pass between the opposed surfaces of the semispinalis colli and complexus, give branches to these muscles, and perforate the inner part of the tendons of the splenius and trapezius, to terminate in the skin at the lower part of the nape of the neck.

The posterior branches of the seventh and eighth cervical nerves pass either through the deep-seated fibres of the semispinalis colli, or between it and the multifidus spinæ, give branches to these two muscles, perforate the tendons of the trapezius and splenius, and terminate by ramifying, the one on the skin above the scapula, the other over the integument, as far as about the spinous process of the third dorsal vertebra. The inter-transversales muscles, cervicalis ascendens, trachelo-mastoid, and transversalis colli, receive numerous small filaments from these nerves almost immediately after their appearance in the neck.

The posterior branches of the dorsal (thoracic) nerves are much smaller than the anterior, and are directed backwards between the ascending costo-transverse ligaments and the sides of the vertebræ. Having reached the outer border of the semispinalis dorsi and multifidus spinæ, they divide into external and internal branches, the latter being muscular and cutaneous in their distribution, the former only muscular in the eight upper. In the first eight the internal branches are larger, in the last four much smaller than the external.

The external or muscular branches of the eight superior pass between the sacro-lumbalis and longissimus dorsi, and give off numerous filaments to supply these muscles, and the levatores costarum; that of the first sending a few filaments to the cervicalis ascendens, trachelo-mastoid, transversalis colli, and scaleni muscles.

The internal branches wind either over the posterior aspect of the semispinalis dorsi, or between it and the multifidus spinæ, and having supplied these muscles with numerous filaments, reach the sides of the spinous processes; here they perforate the rhomboid, latissimus dorsi, and trapezius, the last muscle very obliquely, and become cutaneous, being principally distributed to the skin at the back part of the scapular region.

The external branches of the four inferior pass obliquely downwards and outwards between the sacro-lumbalis and longissimus dorsi, communicating with each other in their course, and at the outer border of the former muscle perforate the tendon of the latissimus dorsi, and become cutaneous, some of the lower filaments being capable of being traced over the glutæal region.

The internal branches of the four inferior are remarkably small, and are lost either in the substance of the multifidus spinæ, or semispinalis dorsi. The cutaneous filaments from the posterior branches of the dorsal nerves given off on the one hand from the internal, and on the other from their external divisions, are situated somewhat in a line with the angles of the ribs, so that they become more external in proportion to their inferior position.

The posterior branches of the lumbar nerves are analogous in their distribution to the four lower dorsal branches, having an external large musculo-cutaneous, and small internal muscular divisions. *The external branches* run along the deep surface of the longissimus dorsi, and at its outer edge perforate the tendon of the latissimus dorsi, and terminate in cutaneous filaments directed over the crest of the ileum to the glutæal region, as far as on a level with the great trochanter. *The internal branches* are lost in the substance of the multifidus spinæ.

The posterior branches of the sacral nerves exist as distinct branches within the spinal canal, and consequently differ from the cervical, dorsal, and lumbar, which become distinct trunks after the main trunks have issued from the spinal or intervertebral foramina. They decrease in size from above downwards, being extremely small, and passing out of the posterior sacral foramina, the fifth coming out between the sacrum and coccyx. They form a minute anastomosis with each other, and with the corresponding branch of the last lumbar, and after having given filaments to the lower part of the erector spinæ, perforate the tendon of that muscle, and are distributed to the skin over the sacrum and coccyx, and immediately around the anus.

The anterior branches of the spinal nerves are much larger than the posterior branches, the two upper cervical forming the only exception. They form intricate plexuses in the neck, the lower part of the spine and sacrum, the nerves given off from those in the first situation being principally intended for the neck and upper extremities ; in the two last for the lower extremities. The intervening series represented by the thoracic nerves, being comparatively simple in their distribution, do not form plexuses.

The Anterior Branches of the Cervical Nerves.

The anterior branch of the first cervical nerve, smaller than the posterior, is directed between the occipital bone and the transverse process of the atlas, passes over the outer edge of the vertebral artery, and appears at the inner side of the rectus capitis lateralis. It then descends, and forms an anastomotic arch with the anterior branch of the second, in front of the transverse process. In its course the rectus capitis lateralis, and rectus capitis anticus minor receive one or more filaments, and it also sends a filament into the canal for the vertebral artery, and which communicates with the trunk of the second cervical between the transverse processes of the atlas and axis. From this anastomotic arch are given off filaments which communicate with the lingual and par vagum and superior cervical ganglion of the sympathetic.

The anterior branch of the second cervical nerve, also much smaller than the posterior passes forwards between the transverse processes of the atlas and the axis, being concealed by the levator anguli scapulæ, splenius, and first inter-transverse muscle, and divides into an ascending branch, passing in front of the transverse process of the atlas, to communicate with the first cervical; and a descending branch.

The descending branch soon subdivides, and gives several filaments of communication with the superior cervical ganglion; one small filament to communicate with the par vagum, another enters the rectus capitis anticus major, and the last concurs to form the cervical plexus.

Anterior branch of the third cervical nerve, larger than the posterior, and twice as large as the preceding, passes between the vertebral artery and inter-transverse muscles, and having given branches to the levator anguli scapulæ and rectus capitis anticus major, communicates above with the descending branch of the second, below with that of the fourth, and in the interval with the superior cervical ganglion, and then again bifurcates to enter into the formation of the cervical plexus.

The anterior branch of the fourth cervical nerve, of the same size as the preceding, communicates above with the third, below with the fifth cervical, in the middle with the superior cervical ganglion, and then enters into the formation of the lower part of the cervical plexus.

The cervical plexus (the deep cervical plexus) is composed of the primary and secondary anastomosing arches of the anterior branches of the four upper cervical nerves. These anastomosing arches are subject to considerable variation, though generally formed by each nerve bifurcating, and, after having communicated with the nerve above and below, again reuniting in a more or less uniform manner prior to giving off their terminal branches. The plexus is situated deeply at the upper anterior and outer part of the neck behind the posterior edge of the sterno-mastoid, in front of the scalenus posticus, external to the rectus capitis anticus major, the carotid artery, jugular vein, and par vagum. It constitutes the chief contents of the posterior superior cervical triangle, and is surrounded by a large quantity of loose cellular membrane, absorbent glands, and fat, and immediately invested with a prolongation of the deep cervical fascia, which renders the dissection of the numerous branches as they immediately proceed from it, difficult. It communicates internally by several delicate filaments with the superior and middle cervical ganglia of the sympathetic; below with the upper part of the brachial plexus, and externally with the spinal accessory, giving several filaments to the muscles with which it is in immediate relation. The branches given off from the cervical plexus may be divided as follows, into

$$\text{Superficial ascending}\ \begin{cases}\text{Superficialis colli.}\\ \text{Auricularis magnus.}\\ \text{Occipitalis minor.}\end{cases}$$

Superficial descending	Supra-clavicular. Supra-acromial.
Deep - - -	Communicating branches. Muscular. Phrenic.

The superficialis colli (superficial cervical nerve) takes its origin from the middle of the plexus in company with, but anterior to the great auricular, the anastomosing branches of the second and third cervical nerves concurring to form it. It emerges from behind the posterior border of the sterno-mastoid about the middle of the neck, and is directed horizontally forwards and inwards, behind the external jugular vein, and between the sterno-mastoid and platysma, and at a variable point divides into two branches, an ascending and descending, the former larger than the latter.

The ascending branch almost immediately divides into numerous filaments, some of which supply the platysma myoides; one or two ascending along the external jugular vein. The greater number are directed upwards and forwards to the upper part of the platysma and digastric muscle, communicate with the deeper seated filaments given off from the portio dura, and becoming cutaneous, supply the skin over the region of the sub-maxillary gland, the chin (communicating with the submental nerve), and the lower part of the cheek; some filaments being directed to the median line to communicate with the corresponding nerve of the opposite side.

The descending branch forms a loop, the concavity of which looks upwards and inwards, perforates the anterior part of the platysma, a little above the middle of the neck, gives off one or two twigs to accompany the anterior jugular vein, and terminates in the skin about the hyoid bone.

The auricularis magnus (the auricular nerve) arises in common with the trunk of the superficial cervical from the anastomosing branches between the second and third cervical. It emerges from behind the posterior border of the sterno-mastoid, above the superficial cervical, and in front of the occipitalis minor. It winds round the edge of the sterno-mastoid, and is directed along it obliquely upwards and inwards to the lower part of the parotid gland on a level with the angle of the jaw, reaches to the anterior border of this muscle, and divides into *a superficial and deep terminal branch.* It gives off before dividing several filaments between the parotid gland and the skin, and others which pass through the substance of the former to terminate in the skin in the malar region, where it communicates with the facial nerve.

The superficial branch courses upwards in the parotid fascia, and on a level with the antitragus divides into several filaments, which are distributed on the one hand to the concave surface of the auricle, particularly the concha; and on the other, to the anterior border of the helix, and the vertical groove in front of it.

The deep branch (anterior mastoid), having perforated the parotid gland, and crossed the auricular branch of the facial, with which it communicates, becomes placed behind the auricle of the ear, ascends along the anterior part of the mastoid process, communicates with the occipitalis minor, and terminates by supplying the skin at the back of the ear, some filaments passing on to its upper border.

The occipitalis minor (mastoid, external occipital) comes from the posterior part of the cervical plexus, taking its origin from the second cervical. It appears at the posterior edge of the sterno-mastoid, behind and above the great auricular. It passes upwards parallel with the great occipital nerve directed by the border of the splenius, which it occasionally perforates, to the occipital region behind the mastoid process; communicates with the great auricular externally, and with the great occipital nerve internally, and ends by terminating in the skin over the parietal bone. There occasionally occurs a small accessory nerve, between the auricularis magnus and occipitalis minor. This is directed along the posterior border of the sterno-mastoid, and is distributed to the skin over the mastoid process.

The supra-clavicular and acromial nerves, form the termination of the cervical plexus, and exist as two primary trunks, which usually about the level of the posterior belly of the omo-hyoid, divide and subdivide into numerous branches, which traverse superficially the posterior inferior triangle of the neck, first passing behind the platysma, then between it and the skin. The internal series (*sternal*) are directed forwards and inwards, over the lower part of the sterno-mastoid, the inner third of the clavicle, and end in the skin over the upper part of the sternum, and upper and inner part of the pectoralis major. The middle filaments (*mammary*) pass over the centre of the clavicle, and are distributed to the skin of the pectoralis major and the mammary gland, and communicate with branches of the intercostal nerves. The posterior (*clavicular*) pass downwards and outwards over the outer third of the clavicle, and ramify in this skin over the anterior and outer part of the deltoid.

The acromial nerves are larger than the clavicular, and are, ordinarily, two in number. They pass obliquely outwards, downwards, and backwards, over the lower part of the superficial aspect of the trapezius, give some filaments to this muscle, which communicate with the spinal accessory nerve, and having reached the acromion, divide into numerous cutaneous branches, which are lost in the skin covering the spine of the scapula, and the outer and back part of the deltoid.

The communicating branches have been already partly described in the consideration of the formation of the plexus; and are formed by different filaments, which are connected with the trunk of the sympathetic, its upper and middle cervical ganglion, as also with the par vagum and lingual. The internal deep branch is represented by the *communicans noni* or *internal descending cervical.* It takes its origin principally from the descending division of the second cervical, and having received a filament from the first cervical, comes down the neck external and posterior to the internal jugular vein. At the middle or lower third of the neck, it describes a curve; the concavity of which looks upwards, and communicates with the descending branch of the lingual (descendens noni), by winding in front of the internal jugular vein. This nerve is subject to considerable variation, bifurcating, occasionally, before communicating with the descendens noni, and giving off now and then one or two delicate filaments to the same muscles, usually supplied by the latter nerve: viz. the sterno-hyoid, sterno-thyroid, and omo-hyoid. The external communicating branches are represented by a rather larger *anastomotic branch*, which communicates at an acute angle with the spinal accessory; and by the *muscular branches*. These accompany the spinal accessory, communicate more or less with it, and are distributed to the trapezius, levator anguli scapulæ, the rhomboideus minor, and upper part of the rhomboideus major.

The phrenic nerve (diaphragmatic, internal respiratory) appears at the lower and anterior part of the fourth cervical nerve of which it appears the continuation. It receives, however, some accessory filaments from the third and fifth cervical, which exist either as single or plexiform twigs, or are occasionally absent. The secondary sources of origin are, in fact, subject to considerable variation. It is directed along the anterior edge of the scalenus anticus, inclining slightly inwards between the subclavian artery and vein, before entering the superior opening of the thorax. It passes behind and outside the carotid artery and jugular vein, and communicates with the fifth, sixth, and, occasionally, with the seventh cervical and pneumogastric nerves, and invariably with the sympathetic. The exact points of communication of these different nerves is by no means determinate; sometimes taking place in the neck; at others, in the upper part of the chest. It crosses the direction of the internal mammary artery, and reaching the anterior mediastinum, glides down in front of the root of the lung between the pericardium and inner aspect of the former, and terminates in the diaphragm. In its course within the chest, it gives several filaments to the remains of the thymus gland; some very minute twigs of communication with the superior cardiac plexus; and receives, occasionally, a very delicate filament of communication, coming down obliquely, from the descendens noni: on reaching the diaphragm, the nerve divides into a series of superior and inferior filaments; the former, long and diverging from each other, enter the upper surface of the muscle, having first passed for some distance between the muscle and the pleura covering it; the latter perforate the muscle, diverge, and run for some distance between the muscle and peritoneum, and enter its under surface.

The right phrenic is shorter and more vertical in direction, and more anterior in its position than the left, being directed in the upper part of the chest, along the vena cava superior. Several of its internal terminal filaments pass behind the vena cava inferior, communicate with the left, and end in the cœliac plexus; a few, however, communicate, also, with some twigs of the pneumogastric.

The left phrenic turns over the apex of the heart; and, besides its general distribution, gives filaments to the crura of the diaphragm, anastomosing filaments to the solar and cœliac plexus, and some communicating branches to the opposite nerve.

The anterior branches of the four inferior cervical and first dorsal nerves are very large, and form, therefore, a remarkable contrast to the four upper cervical, situated above them. They pass through the intervertebral foramina, between the two scaleni; the eighth cervical passing between the foramen common to the last cervical and first dorsal vertebra. Having given off several filaments to communicate with similar filaments from the inferior and middle cervical ganglion, and some small twigs to the scaleni, the different branches unite together, so as to constitute the brachial plexus; the first, communicating above with the fourth cervical, and sending a twig to the phrenic. The union of the different branches takes place in the following manner: — the anterior branches of the fifth and sixth descend obliquely outwards, and, after a course of about one or two inches, unite at an acute angle. Those of the eighth cervical and first dorsal, which are not so oblique in their direction, similarly unite; but a little more internally: this union taking place, occasionally, between the scaleni, either pair of branches almost immediately bifurcating after their union. The trunk of the seventh passes distinct between the two upper and lower branches, as far as the lower border of the clavicle in the upper part of the axilla, and there bifurcates; the upper part of the bifurcation being connected with the lower part of the bifurcation of the first united cord, and the lower with the upper of the last united cord. Secondary bifurcations and anastomoses take place at more or less acute angles, and thus the brachial plexus is constituted.

The brachial plexus (axillary) is situated at the inferior and lateral part of the neck, in the posterior inferior cervical triangle, where it is covered in by a considerable quantity of fat, cellular membrane, and lymphatic glands, which separate it from the external jugular vein. The scalenus anticus bounds it in front and internally; the scalenus posticus in the opposite direction; and in its course from between these muscles to the clavicle, it is crossed by the omo-hyoid muscle, transversalis coli, and humeral vessels, and more superficially, by the supra-clavicular and acromial branches of the cervical plexus. Having passed from beneath the clavicle, it becomes placed between the coracoid process of the scapula and the first digitation of the serratus magnus, and anterior and external to the first rib, and there divides into its terminal branches. In the neck, the plexus is situated superior, posterior, and external to the artery; but as the trunks gradually converge towards the axilla, and the terminal branches again diverge, the artery comes to be bounded by some internally, by others externally. The plexus is broad above, where it represents the base of a triangle, and narrow below at its termination at the upper part of the axilla.

The different branches of the plexus may be divided into those given off above, and those below the clavicle: — the former, for the levator anguli scapula, subclavius, rhomboid, and serratus magnus; the latter, for the upper extremity and its muscles.

Supra-clavicular	Muscular, supra-scapular. Subscapular.
Infra-clavicular	Internal cutaneous. External cutaneous. Median. Ulnar. Musculo-spiral. Circumflex.

Of the muscular branches. *The nerve for the rhomboideus* takes its origin from the anterior branch of the fifth cervical, immediately after it has quitted the intervertebral foramen; but is frequently given off from the cervical plexus: it is, consequently, deeply seated. It either perforates the scalenus porticus or winds round it, to get between it and the levator anguli scapulæ; continues along the costal surface of the latter muscle, and then passes to the same surface of the rhomboideus, as far as its lower part, frequently supplying, in its course, the levator anguli scapulæ, which, in many cases, however, receives filaments from a distinct nerve arising above it, and taking a similar course.

The nerve to the serratus magnus (external respiratory, posterior thoracic), situate at the posterior and upper part of the plexus, arises from it by two delicate roots, which come off from the lower edge of the fifth and sixth cervical, immediately after they have passed the intervertebral foramina. It receives, sometimes, a twig from the seventh. It is directed downwards and outwards, and reaches the thorax between the subscapularis and serratus magnus, passing behind the axillary vessels. It passes along this muscle inferior, to the long thoracic artery, and terminates in its lower part, by numerous filaments.

The nerve for the subclavius is very small, but always present, and is given off from the anterior part of the united trunk of the fifth and sixth cervical. It passes down anterior to the subclavian artery, and enters the middle of the muscle.

The remainder of the muscular branches are very small, and come off from the lower and anterior part of the plexus, being principally derived from the seventh cervical: some pass behind, and others, in front of the axillary artery, enter the axilla, and are distributed to the posterior surfaces of the pectoralis major and minor. They are known under the collective name of *anterior or short thoracic.*

The supra-scapular nerve, larger than the long thoracic, issues from the upper and back part of the plexus, from the united root of the fifth and sixth cervical at their angle of union. It is directed downwards, outwards, and backwards in company with the supra-scapular vessels, passes behind the trapezius and coracoid process to the notch in the upper edge of the scapula, beneath the ligament which converts this notch into a foramen, and which separates it from the supra-scapular vessels. Having reached the supra-spinal fossa, and supplied the supra-spinatus muscle, it winds along the concave external border of the spine, and reaches the infra-spinal fossa, supplying the infra-spinatus. From the inferior filaments one or two twigs can be traced to the teres minor.

The subscapular nerves are intended for the latissimus dorsi, teres major, and subscapularis. That for the first muscle is the largest and longest. It arises from the plexus above, and internal to the circumflex nerve, passes down in the axilla between the subscapularis and serratus magnus, parallel, but posterior to the long thoracic, and terminates by reaching the lower border of the latissimus dorsi, where it enters its substance. It gives off occasionally in its course the branch from the teres major, which usually, however, arises from the plexus below it. This nerve passes downwards and outwards at the subscapularis, and enters the anterior surface of the teres major.

The nerves for the subscapularis are: a small one, generally constant as to its origin arising high up from the same source of origin as the circumflex, passing behind the axillary artery to the upper part of the superficial surface of the subscapularis; the other larger, and frequently derived from the circumflex, to be distributed to the middle of the muscle.

The internal cutaneous, the smallest of the terminal branches of the brachial plexus, and situated most internally, takes its origin principally from the last cervical and first dorsal. It descends, covered in by the brachial aponeurosis, along the inner aspect of the arm, between the median and the ulnar, and concealed above by the axillary artery. Deeply seated in the axilla, in leaving this cavity it inclines slightly forwards and outwards in company with, but anterior to, the basilic vein; and at a variable distance from the elbow joint, generally a little below the middle of the arm, divides into *external and internal cutaneous branches:* both of which perforate the fascia. In this part of its course the internal cutaneous gives off in the axilla a small cutaneous filament, which, having communicated with the second or third intercostal nerve, perforates the fascia, and supplies the skin on the inner part of the arm as far as the internal condyle.

The external terminal branch, the continuation of the trunk in the arm, and the larger of the two, divides into two or three twigs, which pass either in front or behind the median basilic vein, some occasionally passing in front, and some behind. The external filaments course down the anterior and inner part of the fore-arm, following the direction of the median vein, and communicating with branches of the external cutaneous: the internal follows the course of the ulnar vein, communicating with a twig of the ulnar nerve at the lower part of the fore-arm. Both terminate in the integument over the annular ligament.

The internal branch, frequently perforating the fascia lower down than the external, passes behind and then below the median basilic vein, to the inner and back part of the fore-arm, and having communicated a little below the elbow with the accessory internal cutaneous, continues its course, and supplies the integument along the inner and back part of the fore-arm as far as the inner edge of the hand, communicating, in its course, with the innermost filaments of the external branch.

Placed behind and internal to the internal cutaneous nerve, is the *cutaneous nerve of Wrisberg* (the accessory nerve of the internal cutaneous), considerably smaller than it. It arises from the united chord formed by the seventh cervical and first dorsal. It descends along the inner part of the axilla, and communicates with the cutaneous branch of the second intercostal. Coursing down the arm on a plane behind the ulnar and internal to the basilic vein, it perforates the fascia about the lower third, and, becoming cutaneous, divides into anterior filaments, communicating with the internal cutaneous: and posterior, communicating with the internal cutaneous branch of the musculo-spiral.

The external cutaneous (musculo-cutaneous: perforans casserii), larger than the preceding, but smaller than all the other nerves, and most external, is formed by the fifth and sixth cervical. It is directed obliquely downwards and outwards in front of the tendon of the subscapularis to the inner aspect of the coraco-brachialis, perforates this muscle (occasionally, however, passes behind it without perforating), and then becomes situated obliquely between the biceps and brachialis anticus. At a short distance from the elbow it emerges from beneath the outer border of the biceps, and internal to the supinator longus; and at the bend of the elbow, after passing behind the median cephalic vein, bcomes subcutaneous. In this part of its course the external cutaneous nerve gives off a series of muscular branches. Of the two *branches to the coraco-brachialis*, the upper, having perforated it, terminates in the short head of the biceps.

The branches to the biceps unite separately or by a common trunk, and one of them perforates the biceps, and supplies the elbow-joint, being here situated to the outside of the superficial flexor tendons.

The branches for the brachialis anticus are several, and penetrate the muscle by its superficial surface. The continuation of the external cutaneous nerve in the fore-arm is represented by a series of *internal and external cutaneous branches*, which pass down along either side of the radial vein. *The former* near the wrist joins with a branch from the radial nerve, and gives off a filament which perforates the fascia, and accompanies the radial artery to the outer and back part of the wrist, where it supplies small twigs to the front and back of the radio-ulnar articulation. *The latter* gives filaments to the outer and back part of the fore-arm, as far as the wrist.

The median nerve. — The largest of the brachial plexus, and situated between the external cutaneous and the ulnar, arises by two roots, the external common to the median, and the external cutaneous: the internal common to the median, the internal cutaneous, and the ulnar. The fifth, sixth, seventh, and eight cervical and first dorsal nerves consequently concur to form it. Between its two roots is placed the axillary artery. It passes along the inner side of the arm in company with the axillary artery to the bend of the elbow, lying at first to the outside of the vessels, and then a little above the middle of the arm, crosses to its inner side, occasionally, however, continuing all along to its outside. It is slightly overlapped by the inner border of the biceps, having the brachialis anticus to its outside: the latter muscle separates it inferiorly from the ulnar nerve. The upper part of the internal cutaneous nerve runs along its inner side. It sinks into the bend of the elbow behind the semilunar fascia, and in front of the brachialis anticus, passes between the two heads of the pronator radii teres, and is then conducted along the forearm between the flexor digitorum sublimis and profundus to the annular ligament, behind which it passes; and at the lower border of this becomes expanded, and divides into a series of terminal digital branches.

The median nerve gives off no branches during its course along the arm, with the exception of an occasional communicating branch to the musculo-cutaneous below the level of the insertion of the coraco-brachialis; and a branch which is usually found coming off from the anterior part of the trunk a little above the elbow. This is directed along the brachialis anticus to the pronator teres, which it supplies, and sends a few filaments backwards to enter the articulation.

The branches given off in the fore-arm are muscular, interosseous, and cutaneous.

The muscular branches for the lower part of the pronator teres, flexor carpi radialis, palmaris longus, and flexor sublimis, are generally derived from a primary branch, which arises behind the pronator teres a little below the elbow-joint; the lower part of the flexor sublimis, however, receiving several smaller branches from the main trunk. The branches for the flexor longus pollicis and flexor digitorum profundus are given off lower down, there being generally one for the former and two for the latter, the outer part of which only is supplied; the inner part of the muscle being supplied by the ulnar nerve.

The anterior interosseous nerve is the most deeply seated branch of the median, coming off at an acute angle from the trunk, between the origin of the deep-seated muscular branches. It runs vertically downwards in company with, but to the radial side of, the corresponding artery, in front of the interosseous membrane between the flexor digitorum profundus and flexor longus pollicis, giving on either side small filaments to them. Having reached the upper edge of the pronator quadratus, it passes behind that muscle, and terminates either by sending numerous filaments into its posterior surface, or, after having supplied it, perforates the lower aperture of the interosseous membrane, and reaches the back of the carpus.

The palmar cutaneous branch is given off at the lower fourth of the fore-arm, passes forwards from beneath the tendons of the flexor sublimis, and behind the fascia, which it perforates a little above the wrist, and divides into an external filament, which, having communicated with the radial, terminates in the skin of the vola major, and an internal descending over the annular ligament to be lost in the skin of the upper part of the palm.

The terminal digital branches of the median are derived from two primary branches, into which the flattened and expanded nerve divides, after having passed from beneath the annular ligament. These are external and internal, the former supplying the muscles of the thumb, and sending off three digital branches for the thumb and radial side of the index finger, and rather smaller than the latter, which gives off two digital branches for the opposed sides of the index and middle, and the middle and ring finger. The *muscular branch* passes in a slightly curved manner outwards and upwards, and terminates in filaments for the supply of the abductor, opponens and flexor brevis pollicis.

The first digital nerve is directed obliquely downwards and outwards in front of the tendon of the flexor longus pollicis, and near the head of the metacarpal bone, crosses it to its outer side, and continues its course to the extremity of the outer side of the anterior aspect of the first phalanx, where it terminates in dorsal and palmar branches. The dorsal branch winds on to the back of the last phalanx, communicates with the radial, and supplies the skin at the root of the nail; the palmar continues in the original course of the nerve to the skin at the extremity of the thumb.

The second digital nerve, not so oblique in its direction as the first, crosses over the adductor pollicis, gives a filament to it, and is conducted along the inner side of the flexor longus pollicis tendon to the ulnar side of the thumb, sending in its course some filaments backwards to communicate with the dorsal branches of the radial, and terminating in a similar manner to the preceding branch.

The third digital nerve is directed in front, and to the outside of the first lumbrical muscle, gives a filament to it, and reaches to about the middle of the outer side of the proximal phalanx of the index finger, where it divides into dorsal and palmar branches. The dorsal branch passes on to the back of the phalanx, communicates with one of the dorsal cutaneous nerves, to form a nerve which ends in the integuments of the back part of the last phalanx: the palmar branch passes in the original direction of the nerve, and terminates on the outer side of the distal phalanx by again dividing into palmar and dorsal branches, having a similar distribution to the two first nerves.

The fourth digital nerve passes in front of the second interosseous space, gives a filament to the second lumbrical muscle, and about the middle of this space divides into two branches, which are directed along the opposed sides of the middle and index fingers. The *fifth* passes downwards and slightly inwards in front of the third metacarpal space, gives a filament to the third lumbricus, communicates by a delicate filament with the ulnar, and at the middle of this space terminates in two branches for the opposed sides of the middle and ring finger. The termination of the divisions of the fourth and fifth digital nerves, and the branches given off from them, are exactly similar in distribution to the third digital nerve, giving off, like it, on the proximal and distal phalanx, a dorsal branch. Each of the digital nerves, although running along the sides of the fingers, and giving off in their course numerous cutaneous filaments, which are directed towards the axes of the fingers, are not observed to anastomose with each other.

The median nerve in the palm of the hand is situated on a plane anterior to all the flexor tendons, and the trunk before dividing is situated half an inch or more above the level of the superficial palmar arch of arteries which crosses in front of its three internal branches. The accompanying digital arteries are placed somewhat behind, and further from the longitudinal axes of the fingers than the nerves, which, however, in their course send numerous small filaments which wind around them.

The ulnar nerve, somewhat smaller than the median, arises from a trunk common to it, the internal cutaneous and the inner head of the median. The first dorsal and last cervical are consequently principally engaged in forming it. Almost immediately after its origin it is directed slightly inwards and outwards from the median, and behind the internal cutaneous, and at the lower part of the axilla appears deeply seated at the inner aspect of the arm, being directed in front of the triceps extensor muscle. Below the level of the coraco-brachialis it perforates the internal intermuscular septum, and becomes surrounded by several fasciculi, derived from the inner head of the triceps, and passes behind the intermuscular septum to gain the space between the internal condyle and olecranon, being here situated between the two heads of the flexor carpi ulnaris. It now inclines downwards and slightly outwards along the inner part of the coronoid process of the ulna, and then takes a vertical course down the fore-arm, covered over by the flexor carpi ulnaris, and between it and the flexor digitorum profundus. It gradually inclines to the surface, and at the lower third of the fore-arm becomes sub-aponeurotic, and passes from between the flexor carpi ulnaris and inner tendon of the flexor sublimis to the lower part of the anterior surface of the annular ligament, passing along it in a distinct sheath with the artery, in close contact with, and external to, the pisiform and unciform bones, and divides into its terminal branches. In the upper part of the arm the ulnar nerve is in relation with the axillary artery, which is placed between it and the median, nearer however the latter. In the upper part of the fore-arm it is about half an inch or more distant from the artery, but gradually inclines, so as to come in close relation with, but internal to it, in the two lower thirds of the fore-arm, and in the palm of the hand.

The ulnar gives off no branches in the arm; and the first that comes off from it, is when the nerve is placed between the two heads of the flexor carpi ulnaris. There are several small articular filaments which enter the inner part of the joint, and three or four which are distributed to the above muscle. In the upper third of the fore-arm some filaments are again given off to the flexor carpi ulnaris, and others for the supply of the inner half of the flexor digitorum profundus. About the middle a small branch is given off, which, after sending satellite filaments to accompany the ulnar artery, perforates the fascia, and becomes cutaneous to communicate with the internal cutaneous. The largest branch, however, given off from the ulnar, comes away about two inches above the wrist-joint, and is named, its *dorsal branch* (dorsalis carpi ulnaris: internal dorsal nerve). This winds downwards and inwards, and having passed between the tendon of the flexor carpi ulnaris and the bone, perforates the fascia at the back of the fore-arm, and becomes cutaneous a little above the styloid process. It runs then along the inner edge of the carpus; and on the posterior annular ligament terminates in two branches. The *inner branch* passes along the inner and back part of the metacarpal bone, and phalanges of the little finger, supplying the integument as far as its extremity, and sending in its course some small filaments to the abductor minimi digiti. The *outer branch* crosses obliquely the tendon of the extensor minimi digiti, and on the fourth interosseous space sub-divides. The inner sub-division at the extremity of the space bifurcates in order to supply the opposed sides of the little and ring finger. The outer sub-division at the lower extremity of the third interosseous space having communicated with the dorsal branch of the radial, similarly bifurcates for the supply of the integument of the opposed sides of the middle and ring finger. The dorsalis carpi ulnaris, independently of the above branches, sends numerous filaments to the inner and back part of the wrist and hand, and communicates above with the external or posterior cutaneous.

The terminal branches of the ulnar nerve are two in number, *a superficial external, and deep internal.*—The former, after a very short course, divides into two branches, a small internal, and large external. The *internal branch* passes along the ulnar side of the little finger to its extremity, giving filaments in its course to the muscles of the little finger. The *external* passes obliquely across the flexor tendons for the ring finger, gives a filament to the fourth lumbricus, and one of communication with the median, and over the fourth interosseous space at a variable distance from its inferior extremity bifurcates: the divisions of the bifurcation being distributed in a similar manner with the median to the opposed surface of the ring and little finger.

The deep branch is directed backwards and outwards between the abductor minimi digiti, and the flexor brevis to the posterior aspect of the adductor minimi digiti, having first given off on the palm a small branch which sends filaments to these three muscles. It passes downwards in a curved manner, the convexity of the curve looking downwards and inwards, and after a short course passes at an acute angle behind the deep palmar arch of arteries. No branches come off from its concavity. From its convexity and back part and outer termination are derived filaments which supply the two inner lumbricales, the palmar and dorsal interossei, the adductor and flexor brevis pollicis. The deep or perforating interosseous branches can be traced through the two layers of interossei to the skin on the back of the hand, where they communicate with the dorsal cutaneous from the radial and ulnar nerves.

The musculo-spiral nerve (*radial*) slightly larger than the median, arises from the inner and back part of the plexus, and is formed particularly by the three inferior cervical and first dorsal nerves. The trunk from which it arises also gives origin to the circumflex nerve. It passes at first from before backwards, running behind the ulnar, and in front and below the circumflex nerve, and having crossed the conjoined tendons of the teres major, and latissimus dorsi, inclines downwards, backwards and outwards to the posterior surface of the humerus, between it and the long head of the triceps. It continues gradually inclining more outwards, till it reaches the lower third of the arm where it gains the outer aspect of the bone, and here it passes forwards in company with the superior profunda artery, to the anterior and outer aspect of the arm lying internal to the outer head of the triceps which it perforates. It is now directed between the supinator longus and brachialis anticus, and then between the latter and extensor carpi radialis longior, and, having reached the outer and anterior part of the elbow-joint, divides into an anterior and posterior terminal branch.

The branches given off from the musculo-spiral in the arm are numerous, and may be arranged into

Internal	Internal cutaneous. Branch for the internal head of the triceps.
Posterior	Branches for the long head of the triceps. Outer head and anconæus.
External	Cutaneous filaments to the arm. External cutaneous.

The internal cutaneous is the first branch of the musculo-spiral, and continues for some distance deeply seated to the fascia, which it perforates above the middle of the arm, and descends as one or two filaments along the inner and back part of the arm to the elbow, where they communicate with the posterior filaments of the accessory internal cutaneous.

The branch for the internal head of the triceps is the next that is given off. It is a delicate, long nerve, which is directed along the surface of the inner portion of the triceps, running behind the ulnar nerve to within three or four inches of the elbow-joint, when it enters the substance of the muscle.

The branches for the long head of the triceps are numerous, and enter its anterior surface. The superior branch is reflected upwards, and can be traced as far as the axillary origin of the muscle. The inferior or descending branch is the longest, and courses downwards to near the olecranon before entering it.

The branch for the outer head of the triceps and anconæus, given off externally to the branches for the long head, is a long slender nerve. It passes down between the outer and middle head to the outside of the olecranon, supplying the outer head in its course, and terminating in the anconæus by entering at its anterior surface.

The external cutaneous branch is given off below the middle of the arm, as the musculo-spiral is commencing its anterior and outer course. It passes along the outer and back of the arm, and divides into two or three delicate descending filaments which supply the skin, and terminate on the back of the carpus between the posterior branches of the external cutaneous, radial, and dorsalis carpi ulnaris with which they communicate.

The musculo-spiral nerve, before giving off its terminal branches, sends filaments to the muscles between which it passes, viz. the brachialis anticus, supinator longus, and extensor carpi radialis longior.

The anterior terminal branch (*radial nerve*) is the apparent continuation of the musculo-spiral nerve, though smaller than the posterior terminal branch. It passes between the supinator longus and brevis, lying on the latter, and over-lapped by the former, and gradually approaches, in its descent of the fore-arm, the radial artery; so that at the middle it is in close contact with, but external to, the vessel. Having arrived at the lower third of the fore-arm, or a little above, it twists round the deep surface of the tendon of the supinator longus, and appears beneath the fascia on the outer part of the fore-arm, and after a short subaponeurotic course, perforates the fascia, and divides about a couple of inches above the styloid process into *an external large, and internal terminal-branch. The external branch* passes along the outer aspect of the styloid process; and at the proximal part of the wrist sends a communicating loop inwards, to be connected with the cutaneous palmar branch of the median. It then descends on the dorsum of the thumb, and supplies its external border. *The internal branch* crosses obliquely the extensor ossis metacarpi and primi internodii pollicis, and divides into a series of branches which supply the ulnar side of the thumb: both sides of the index finger, and the radial side of the middle. These different branches furnish, in their course along the carpus, several cutaneous filaments, and some small twigs which communicate with the perforating interosseous of the deep branch of the ulnar nerve. The most internal division communicates with the dorsalis carpi ulnaris. The two terminal branches of the radial are subject to much variation: the external being sometimes larger than the internal, and supplying either both sides of the thumb, or both sides of the thumb and the radial side of the index finger. The internal branch occasionally unites with the outer division of the dorsalis carpi ulnaris, and supplies the opposed sides of the middle and ring fingers.

The deep terminal branch (*the posterior interosseous or muscular*) is larger than the anterior, passes downwards and backwards along the inner aspect of the exterior carpi radialis brevis, gives filaments to it, and reaches the surface of the supinator brevis, supplies it, as it passes obliquely downwards, backwards, and inwards through its substance, to emerge at its lower and posterior portion. It here divides into a posterior and anterior series: the former supplying the extensor carpi ulnaris, the communis digitorum, and minimi digiti, entering at their anterior aspect the latter the deep-seated muscles. One of the latter has a somewhat remarkable course; is longer and larger than the rest; and passes along the posterior surface of the extensor ossis metacarpi and primi internodii; and at the lower part of the fore-arm becomes placed between the interosseous ligament and the extensor secundi internodii, and indicator, supplies these muscles with one or two twigs, and is conducted in front of the posterior annular ligament to the back of the carpus, where it assumes a gangliform enlargement, from which numerous filaments radiate for the supply of the ligaments and carpal articulations.

The circumflex nerve (*axillary*) is the most posterior of the terminal branches of the brachial plexus, and is occasionally given off from the musculo-spiral, usually, however, taking its origin from a trunk common to it, and to that nerve, external to which it is situated. After a short course in the axilla, it soon leaves that space by passing downwards and outwards over the upper part of the axillary border of the subscapularis to enter the quadrilateral space above the teres major, below the teres minor, and between the humerus and long head of the triceps to terminate in the deep surface of the deltoid. It gives off in this course branches to the subscapularis and teres minor; that for the latter entering the lower border of the muscle, and prior to dividing into its deltoid branches. — *The cutaneous nerve of the shoulder* passes from behind the posterior border of the deltoid, perforates the fascia, and divides into a series of radiating branches, which supply the skin at the upper and back part of the shoulder. *The deltoid branches* ramify through the substance of the muscle as far as its insertion, and from one of them a filament is given off to the capsular ligament of the shoulder joint.

The anterior branches of the dorsal (intercostal) nerves are twelve in number, the first escaping between the first and second dorsal vertebræ, and the last between the last dorsal and first lumbar. They run more or less parallel to each other without forming plexuses, and are destined to supply the thoracic and abdominal parietes, and the skin about the arm and axilla. They present general and special characters. Each branch runs outwards, from its origin, being separated from the posterior root by the intervention of the anterior costo-transverse ligament, to reach the intercostal space, between the pleura and external layer of the intercostal muscles, and below the intercostal vessels. Having communicated by one or two filaments with the thoracic ganglia of the sympathetic, these nerves are continued between the two layers of the intercostals, to about midway between the spine and the sternum, and here they divide into *cutaneous* and *intercostal* branches. The cutaneous branches perforate, in a very oblique manner, the external layer of intercostals; and, after a short course, forwards and outwards, between them and the serratus magnus, either escape between the digitations of the serratus magnus and external oblique, or perforate their fibres, and divide into anterior and posterior branches. This division takes place sometimes when the trunks of the cutaneous nerves are covered by the serratus and oblique. *The posterior branches* are reflected backwards and upwards, and, after a course of an inch or two between the latissimus dorsi and the skin, terminate in the latter. *The anterior branches* are directed downwards and forwards, or horizontally, and, after a longer course than the posterior branches, terminate, like them, in the skin.

The intercostal branches, though somewhat smaller than the cutaneous, represent the continuation of the anterior branches of the dorsal nerves. They continue in the original course of the latter, below the lower edge of the ribs on the one hand, and the costal cartilages on the other; and near the border of the sternum above, and the linea alba below, perforate the muscular fibres, and become cutaneous. The trunks of the intercostal nerves and their continuation give off numerous filaments to the supply of the intercostal muscles, and several extremely delicate twigs, which frequently pass over the inner aspect of the ribs, to communicate above and below with each other in the intercostal spaces.

The special characters of the intercostal nerves are as follow: —

The first dorsal nerve, ascending in front, and across the neck, of the first rib, to assist in the formation of the brachial plexus, gives off only a small intercostal nerve. This comes away soon after the nerve has left the intervertebral foramen, and is directed along the inner surface of the first rib, to the first intercostal space, without giving off a middle cutaneous branch, and passes along the lower edge of the cartilage to the sternum, by the side of which it perforates the intercostal muscles, and terminates on the skin, at the upper and fore part of the thorax.

The second dorsal nerve crosses obliquely over the second rib, external to its neck, to gain the lower part of the first intercostal space, and again crosses the second rib, to reach the second intercostal space on a level with the middle of the former. *Its cutaneous branch* is of large size, and, supplying the arm with cutaneous branches, is named the *intercosto-humeral*, which perforates the second intercostal space. In traversing the axilla it gives off a branch of communication to the accessory internal cutaneous, and one to communicate with the second intercosto-humeral; the latter united nerve sending filaments to the skin at the upper and anterior part of the arm. Two or three filaments represent the termination of the nerve, cross the lower part of the posterior boundary of the axilla, and terminate in the skin, at the upper and back part of the arm.

The cutaneous branch of the third dorsal (the second intercosto-humeral) is smaller than the second, and passes through the third intercostal space: it divides into an anterior and posterior branch; the former winds upwards, forwards, and inwards, over the lower border of the pectoralis major, to terminate in the mamma and integument; the latter, having communicated with the second intercostal, sends filaments to the axilla, and terminal branches, which are directed to the outer and anterior part of the axilla to supply the skin, at the upper and back part of the arm.

The cutaneous branches of the fourth and fifth dorsal nerves send filaments inwards, to supply the mamma; and filaments backwards, over the superficial surface of the latissimus dorsi, to supply the skin over the anterior and outer part of the scapula. The intercostal nerves of the eighth, ninth, tenth, *and eleventh dorsal nerves* perforate the intercostal spaces of the false ribs, pass through the costal attachments of the diaphragm, to get between the external and internal oblique, as far as the border of the rectus, where they give off small cutaneous branches. Entering the sheath of the rectus, they proceed along the posterior surface of the muscle, and terminate, by giving off some filaments, which ramify in its inner part; and others, which perforate the anterior layer of the sheath, at a variable distance from the linea alba, to supply the skin at the anterior part of the abdomen.

The twelfth dorsal nerve is larger than those that have preceded it, and gives a filament of communication to the anterior branch of the first lumbar nerve. It is directed obliquely downwards and outwards, following the course of the last rib, along the lower border of which it runs, passes behind the anterior layer of the transversalis fascia between it and the quadratus lumborum, and, on a level with the apex of the rib, divides into two branches. *The cutaneous branch*, larger than the abdominal, or continuation of the trunk, perforates, obliquely, the external and internal oblique, gives them some small branches, and then becomes superficial, crosses over the crest of the ilium, and divides into a series of divergent filaments, which lose themselves in the skin of the middle of the glutæal region. *The abdominal branch or continuation of the nerve* passes between the internal oblique and transversalis, supplies these muscles, communicates with the first branch of the lumbar plexus, and terminates in the rectus and pyramidalis, and the skin over them.

The anterior branches of the lumbar nerves are five in number, intervening between the corresponding branches of the dorsal and sacral nerves. They increase in bulk from above downwards, communicate with each other by anastomosing branches, and with the lumbar ganglia by filaments, which come from the latter, or the main trunks. These filaments of communication with the sympathetic, vary in number from two to five, and are in close relation with the convexities of the bodies of the lumbar vertebræ. Several nerves are also given to the supply of the psoas muscle.

The anterior branch of the first lumbar nerve is small, much resembling the anterior branch of the last dorsal. Having quitted the intervertebral foramen, it immediately divides into three branches ; two external and small, viz. : — *the great and small musculo-cutaneous;* the other internal and vertical in direction, and forming *the anastomosing branch with the second.*

The anterior branch of the second lumbar nerve, twice as long and broader than the first, gives off the *genito-crural* and *external cutaneous*, and communicates by a long anastomosing branch with the third.

The anterior branch of the third lumbar nerve, nearly twice as large as the second, is directed downwards and outwards, and gives off, at an acute angle, a large external branch, concurring to form the *anterior crural*, and an internal, the *obturator nerve:* it communicates with the fourth nerve by one branch connected with the main trunk, or by two connected with its two branches.

The anterior branch of the fourth lumbar nerve is somewhat larger than the third. It divides into an external branch connected with the *external* division of the third, to complete *the anterior crural;* and *internal* to assist in the formation of the obturator. Its terminal branch is the anastomosing branch with the fifth, internal to the other two, and vertical in direction.

The anterior branch of the fifth lumbar nerve is the largest of all the series, and terminates in the sacral plexus, and is named the *lumbo-sacral nerve.*

The lumbar or lumbo-abdominal plexus is rather intricate, and formed by the anastomosis of the anterior branches of the five lumbar nerves. Placed upon the sides of the lumbar vertebræ between the transverse processes, and enveloped by the fasciculi of the psoas muscle, it presents, when the latter are dissected away from it, an irregularly triangular appearance ; the apex of the triangle being above, and the base below. In the former situation, the nerves forming it are comparatively delicate, and unite with each nearer the vertebral column than the latter ; it communicates above with the twelfth dorsal nerve, through the medium of the "dorso-lumbar," and below, with the sacral plexus, through the medium of the "lumbo-sacral" nerve. The branches given off from it may be divided into *abdominal* and *crural:* the former being given off from its upper ; the latter, from its inferior or terminal portion.

The abdominal series is represented by the *musculo-cutaneous nerves*, and *the genito-crural. The crural series* by the *external cutaneous, crural*, and *obturator.* The musculo-cutaneous nerves are two in number: the upper being three or four times larger than the lower.

The upper musculo-cutaneous (large abdominal, ilio-hypogastric, ilio-scrotal) is the highest of the branches of the lumbar plexus, taking its origin from the first lumbar nerve. It makes its appearance from behind the psoas muscle about an inch and a half below the last dorsal nerve, runs obliquely downwards and outwards across the quadratus lumborum in the subperitoneal tissue, and about an inch above the crest of the ilium, perforates the tendon of the transversalis, and is continued between it and the internal oblique to the middle of the crest of the ilium, where it divides into two branches, an external and internal. The external passes obliquely between the internal and external oblique, and at the anterior-third of the crest of the ilium, winding on to the glutæal region, divides into an anterior and posterior series of filaments ; the one supplying the integument over the tensor vaginæ femoris, the other that over the anterior part of the glutæus medius. The internal branch, or the continuation of the nerve, after a course of an inch or two, communicates with the small musculo-cutaneous by a loop which usually passes round the internal circumflex ilii vessels. It then divides into an abdominal and scrotal branch. The abdominal runs parallel to the corresponding branch of the last dorsal, generally communicates with it, and passes through the tendons of the internal and external oblique, and is distributed to the skin at the inner part of the groin. The *inguinal*, *pubic, or scrotal* branch runs parallel to Poupart's ligament, in company with, but above, the small external cutaneous, reaches the external ring, and divides into internal terminal branches supplying the skin over the pubis; and external ones supplying the scrotum in the male, and the labia pudendi in the female.

The lower musculo-cutaneous (small musculo-cutaneous—small inguino-cutaneous—small abdominal) is a thin delicate nerve, arising generally from the first lumbar, sometimes from the large musculo-cutaneous, is directed downwards and slightly outwards, along the back part of the psoas, a little in front of the inner border of the quadratus lumborum, crosses the iliacus internus about its upper fourth, and reaches the anterior third of the crest of the ileum. There it is lost by communicating with the large musculo-cutaneous, or, as is generally the case, passes after this communication as a very delicate nerve between the internal oblique and transversalis, supplying the lower part of these muscles, but principally the latter, and parallel to Poupart's ligament, perforates the former muscle at the outer ring, and terminates in a manner similar to the pubic or scrotal branch of the upper musculo-cutaneous, in the scrotum and pubic integument.

The genito-crural nerve (external spermatic — internal inguinal) derived from the second lumbar nerve, and sometimes from the communicating branch between the first and second, passes directly forwards to the anterior part of the psoas muscle, along which it descends vertically to the femoral arch. It lies behind the spermatic vessels, and is crossed by the ureter. Having reached Poupart's ligament, it divides into two branches, an internal or genital, and an external or crural. The genital is directed across the external iliac artery (to which it supplies a few filaments) to the chord, lying below it as far as the internal ring. Prior to entering the inguinal canal the transversalis and internal oblique receive a few reflected branches from it. The nerve then accompanies the chord, crosses the epigastric vessels, supplies the cremaster muscle, runs immediately in front of Gimbernat's ligament, and terminates in the scrotal integument in the male, and labia pudendi in the female, supplying also the integument at the upper and inner part of the thigh, and communicating with the inferior pudendal nerve. The *crural branch* (femoral-cutaneous), having given off several delicate filaments to be distributed to the transversalis and internal oblique, crosses the circumflex ilii vessels, passes underneath Poupart's ligament, a little to the outside of the femoral artery, pierces the fascia immediately below the ligament, and becomes cutaneous, supplying the skin of the thigh at the middle part of its upper third. The division of the genito-crural into its terminal branches is subject to considerable variation, sometimes taking place either immediately after it has emerged from within the psoas, or within the psoas directly after its origin from the plexus. The crural division is at times also extremely small, the external cutaneous then having a more extensive distribution than ordinary.

The external cutaneous (external inguinal) is a branch from the second or from the second and third lumbar, or is occasionally derived from the outer part of the crural nerve. It passes from beneath the outer border of the psoas below its middle, runs across the iliacus towards the space between the two spinous processes of the ilium, lying behind the transversalis fascia. It then passes beneath Poupart's ligament, and divides into an interior and posterior branch. The posterior passes outwards and backwards over the fascia, covering the tensor vaginæ femoris, and supplies the integument at the upper, outer, and back part of the thigh. The extent of distribution of this branch is subject to variation, owing to the circumstance of a corresponding branch being occasionally supplied either by the great musculo-cutaneous, or by the genito crural, when the trunk of the external cutaneous itself comes from the anterior crural. In such instances this branch is small and insignificant, if it exist at all. The anterior branch becoming cutaneous about the upper fifth of the thigh, soon divides into an external and internal, directed downwards, over the fascia covering the anterior and outer part of the rectus muscle. The external division terminates in the integument at the middle third of the outer part of the thigh; the internal at the lower third of the thigh, above and to the outside of the patella.

The *crural nerve* (femoral) is by far the largest branch of the lumbar plexus, and is placed in the substance of the psoas muscle between the external cutaneous, and the obturator, below the level of the former and above that of the latter, from which it diverges at an acute angle. It is formed by the union of the second with the outer branch of the third lumbar nerve, by part of the fourth, and generally by their communicating branch. It is destined to supply the integuments of the front of the thigh, and all the muscles at its anterior and outer portion.

Having emerged from the psoas muscle it is directed forwards and outwards between that muscle and the iliacus to Poupart's ligament, under which it passes, and entering the thigh becomes flattened and expanded, and divides into a series of divergent terminal branches, the trunk occasionally bifurcating before so doing.

The nerve in its course within the pelvis is situated behind the iliac division of the transversalis fascia, external to the iliac artery, and gives off a few branches to the psoas and iliacus. Outside the sheath of the femoral vein and artery it is separated from the latter by the intervention of the psoas muscle.

The terminal branches may be divided into *superficial and deep;* the first consisting of the *internal, and middle cutaneous, and branches to the femoral vessels and pectinæus:* the second of *branches* to the *quadriceps extensor cruris,* and the *cutaneous branch of the inner and* *anterior part of the knee and leg*, viz. *the internal saphænus*.

The internal cutaneous nerve (internal musculo-cutaneous) directed along the inner border of the sartorius muscle, perforates the fascia at the lower third of the leg, occasionally perforating the sartorius before so doing. Having given off several cutaneous branches, which form a connexion with the cutaneous branch of the obturator in this situation, it continues its course towards the lower and inner part of the thigh, having previously communicated with a branch perforating the sartorius, and coming from the internal saphænus. From the thigh it passes along the inner edge of the patella, describing a curve, and sending some terminal filaments from its concavity upwards to unite with the middle cutaneous: others, from its convexity downwards, to communicate with the reflected branch of the saphænus itself, and also its accessory branch.

The accessory saphænus nerve (Cruveilhier) takes its origin from the internal cutaneous; from the anterior crural in company with the latter; or from the trunk of the saphænus itself. It soon divides into a *superficial internal branch*, which passes from within the sheath of the sartorius muscles over the femoral vessels, and adductor longus, and at the junction of about the upper with the middle third of the thigh meets with the internal saphæna vein, which it accompanies as far as the knee-joint, in which situation it communicates with the internal saphænus and cutaneous branch of the obturator. The *external branch*, situated behind the level of the superficial, is directed inwards to the femoral artery, runs along its outer part in close contact with it, and accompanies the vessel in Hunter's canal to its lower extremity. It then quits the artery, is directed in front of the tendon of the adductor magnus, to the upper part of the internal condyle of the femur, where it becomes cutaneous, anastomosing with the internal cutaneous above, with the reflected branch of the saphænus below, and sending cutaneous branches over the inner and middle part of the patella. This branch has been termed by Cruveilhier the *satellite nerve of the femoral* artery: and the superficial branch might with equal propriety be denominated the *satellite nerve of the saphæna vein*. The accessory saphænus is subject to considerable variation, both as to size and origin.

The middle cutaneous nerve perforates the fascia three or four inches below Poupart's ligament, crosses the sartorius muscle, and is directed over the inner part of the rectus to terminate in the cuticle over the front of the patella, anastomosing above with the external cutaneous nerve, and below with the internal cutaneous and accessory saphænus. It frequently divides about the middle of the thigh into two branches, which run parallel with each other. The internal and middle cutaneous nerves not unfrequently perforate the sartorius muscle before becoming cutaneous, the first at the middle, the second at its upper part. They are consequently described also as the *inferior perforating cutaneous*, and the *superior perforating cutaneous*.

The nerve to the femoral vessels is very delicate, and arises internal to the internal cutaneous, sometimes however coming off from the lumbar plexus. It is directed downwards and inwards to the femoral vessels, and divides into a series of filaments, one or two of which are directed through the cribriform fascia to the saphæna vein, along which they pass in a tortuous manner till lost by communicating with the internal branch of the accessory saphænus, about the middle of the thigh. The remainder pass, some behind and some in front of the femoral vessels, and terminate at the lower third of the thigh, by uniting with the external branch of the accessory saphænus.

The branches to the pectinæus are directed inwards behind the femoral vessels, and in their course to this muscle generally send a few filaments to the psoas.

The deep-seated muscular branches arise external to the internal saphænus nerve, and behind the superficial already described: and are from within outwards: Branches for the vastus internus and cruræus: branch for the rectus: and branches for the vastus externus, which are the deepest of all.

The branch for the vastus internus (short saphænus), taking its origin in close contact with the internal saphænus, from which it not unfrequently arises, is directed in company with, but external to it, along with the femoral artery. It separates a little below the middle of the thigh from the vessels, and is directed to the external aspect of the vastus internus, to enter it at its lower one third; but before so doing gives off a *superficial articular branch*, which passes in front of the outer border of Hunter's canal; in this situation occasionally communicating either with the cutaneous branch of the obturator, or the outer branch of the accessory saphænus; crosses through the superficial muscular fibres of the vastus to its aponeurotic termination, which it perforates. It is then reflected forwards, upwards, and outwards, and terminates in two or three filaments, one of which passes behind the ligamentum patella, entering the anterior part of the knee-joint; the others pass in front of the patella, to supply the periosteum and skin over it.

The nerve for the cruræus, shorter than that for the vastus internus, enters the upper and inner part of the muscle, extends as far as its lower part, and gives off filaments to the deep-seated portion of the muscle (the subcruræus) to the periosteum and upper part of the synovial capsule.

The branch for the rectus enters the upper part of its posterior aspect, and divides into a superior branch which passes transversely outwards, and a long vertical branch which passes along its inner side to the lower portion.

The branch for the vastus externus frequently arising in company with that for the rectus, is directed downwards and outwards between that muscle and the cruræus, and, in company with the descending branches of the external circumflex artery, enters its inner aspect by two or three divisions, having previously given off a *superficial articular branch.* This filament, the analogue of the corresponding branch of the vastus internus, creeps beneath the superficial muscular fibres, and near the patella becomes cutaneous, some of the terminal filaments passing behind the outer part of the ligamentum patella, others over the patella, where they are lost in the skin and periosteum.

The saphænus nerve (σαφὴς, manifest), the most internal of the deep-seated branches, and arising behind and external to the middle cutaneous, is the largest branch of the crural. It passes downwards and outwards towards the femoral artery, and, about two or three inches below Poupart's ligament, enters its sheath. The nerve first lies outside and behind the artery; but a little before the vessel enters Hunter's canal it gets anterior to it. During the course of the artery downwards and outwards, to enter the ham, the nerve inclines forwards and inwards, and quits the canal, in company with the anastomotic artery, a little above the level at which the femoral vein and artery pass out. It now follows the course of the sartorius lying behind it, to the inner condyle, and one or two inches above the head of the tibia is placed between that muscle and the gracilis, and gives off, before continuing its course, the *cutaneous tibial* or *reflected branch.* This nerve first runs parallel for a short distance with the tendons of the two muscles, then sweeps downwards, forwards, and slightly upwards over the fascia covering them and their tendinous expansions, and across the spine of the tibia to the skin at the upper and outer part of the leg, about two or three inches below the head of the tibia, communicating above with the internal cutaneous.

The continuation of the nerve, or what may be termed the posterior trunk, inclines slightly backwards from between the tendon of the sartorius and gracilis, and on a level with the knee-joint is a little to the inner and back part of the tendon of the latter. Having received its connection with the cutaneous branch of the obturator, it passes in company with the saphæna vein into the region of the leg, inclining slightly forwards to the back part of the inner border of the tibia. Having supplied the integuments at the upper, inner, and anterior part of the leg, it inclines slightly backwards about its middle, sends filaments to communicate with the continuation of the cutaneous branch of the obturator at the posterior part of the leg. It then again inclines forwards, and terminates about three or four inches above the ankle in two branches. The anterior terminal, the smaller of the two, supplies the skin at the lower sixth of the inner and front part of the leg, and over the front of the ankle joint, a few of the branches entering the articulation. *The posterior* terminal, apparently the continuation of the trunk, supply the integuments over the inner malleolus, upper, inner, and back part of the foot.

The saphænus nerve not unfrequently, in its course in the thigh, in company with the femoral artery, gives off, at a variable height, usually however at the lower fourth of the leg, a small branch corresponding more or less with the distribution of the outer division of the accessory saphænus. The internal saphænus nerve first lies behind the corresponding vein; then in front of it to the middle third of the leg, when it again is placed behind it: an inch or two before it divides into its terminal branches, it is again anterior to it, the latter passing over in front, and the other behind.

The obturator nerve, derived from the third and fourth, and sometimes also from their internal intercommunicating branch, is much smaller than the anterior crural, and rounded. It perforates the inner border of the psoas, along which it is conducted to the pelvis, a little below the level of which it runs to between the external and internal iliac vessels. It then passes obliquely behind the external iliac vein, crossing it at a very acute angle, and reaches the obturator foramen in company with, and above, the obturator artery. It passes through this foramen into the thigh, and terminates by dividing into *superficial* and *deep divergent muscular* branches, situated behind the pectinæus and adductor longus. Soon after its origin a small nerve, the *accessory obturator*, is occasionally observed to proceed from the outer part of the trunk. It passes in company with the femoral vein, anterior and internal to it, beneath the femoral arch, over the horizontal ramus of the pubis, and external to the pectinæus. It is then directed a little inwards, and divides into several branches, some of which enter the joint through the anterior part of the capsular ligament; others supply the posterior surface of the pectinæus, and the remainder, as the continuation of the nerve, terminate by communicating either with the upper part of the trunk of the obdurator itself, or with the branch of the nerve destined for the adductor longus.

The obturator nerve, in passing through the subpubic canal, gives off two or three branches to the obturator externus muscle: one penetrating its upper edge, the others its anterior surface. Some *articular filaments* are also sent off in this direction, and accompany some of the branches of the inferior division of the obturator artery, beneath the transverse ligament to the hip-joint. The relation of these filaments as to size and numbers, however, is not constant, being in the inverse proportion to the size and number of branches given off from the accessory obturator, which is not unfrequently absent.

From the *superficial branch* is given off a long filament internally to the gracilis muscle, which runs for about two inches along the outer surface of the muscle before entering it, another to the posterior surface of the pectinæus, which varies in its size according to whether this muscle be supplied by the accessory obturator or not: and a third to the adductor longus, which also enters its posterior surface.

The most important branch, however, is the *long cutaneous branch* which emerges from behind the lower border of the adductor longus muscle, passes in the fascia behind the internal saphæna vein as far as the knee joint, where it perforates the fascia, and becomes cutaneous at the anterior border of the tendon of the gracilis muscle. In this part of its course, a little below the upper third of the thigh, it communicates either with the internal branch of the *accessory saphœnus*, or with a branch occasionally given off from the saphænus itself, and which accompanies the saphæna vein to the knee joint. It gives off cutaneous branches to the middle of the thigh, forming, with the above nerve, a more or less intricate plexus. Having perforated the fascia on a level with the knee joint, above it, or a little below it, it communicates with the trunk of the internal saphænus (being occasionally only in apposition with it), and internal cutaneous nerve. It terminates by being directed downwards and backwards to above the lower part of the poplitæal region, and continues to give off cutaneous branches, till it is lost in the integument at the inner and back part of the leg to within two or three inches of the ankle: having previously sent filaments of communication to the continuation of the saphænus nerve.

The deep branch of the obturator runs generally behind the adductor brevis, and divides into two branches, one ramifying through the centre of that muscle: the other, *for the supply of the adductor magnus*. From the latter is given off a small articular nerve for the knee joint, which is directed downwards and outwards, towards the attachment of the adductor magnus to the linea aspera, perforates this attachment below the middle of the thigh, and is directed with the poplitæal artery into the ham, winding around the artery, and giving off an internal delicate branch, which enters the knee joint through the ligament of Winslow.

The Anterior Branches of the Sacral Nerves are six in number, and escape from the anterior sacral foramina, decreasing in size from above downwards, and presenting, consequently, characters reverse to what obtain in the corresponding branches of the lumbar nerves. They communicate with the sacral ganglia of the symphathetic, the filaments of communication being usually two between each nerve and the sympathetic.

The first nerve, smaller than the lumbo-sacral nerve, extends more obliquely downwards and outwards, and having passed from the first sacral foramen, unites with it at an acute angle, and communicates with the second nerve.

The second nerve, somewhat smaller than the first, passes more obliquely downwards and outwards from the second anterior sacral foramen, and, having communicated with the third, enters the sacral plexus, sometimes bifurcating previously.

The third nerve, about one-third the size of the second, comes from the third sacral foramen, and passes more horizontally outwards to the sacral plexus, having communicated with the second by a delicate filament sent in front of a portion of the pyriformis intervening between it and the second nerve.

The fourth nerve, considerably smaller than the third, passes from the fourth sacral foramen, communicates above and below with the third and fifth nerve, and terminates in three sets of filaments. One, usually in the form of a single trunk, is directed a little downwards and outwards, between the levator ani and the coccygæus muscle, gives branches to them, and finally becomes cutaneous. This filament in its course generally furnishes a small twig which perforates the great sacro-sciatic ligament, and terminates in the skin over the border of the coccyx. A second, as a single small trunk, passes to enter the sacral plexus. The third series anastomose freely with the hypogastric plexus, and then form of themselves a loose kind of interlacement, from which branches are given off to the rectum sides of the bladder, prostate, and vesiculæ seminales, and the vagina in the female. The levator ani generally receives one or two filaments, a distinct twig entering the middle, the other supplying the anterior part, after ramifying on the prostate.

The fifth passes from the fifth anterior sacral foramen, communicates above and below with the fourth and sixth, and sends a filament which perforates the coccygæus muscle, supplies it, and terminates on the skin to the side of it.

The sixth (anterior branch of the coccygæal nerve) is extremely delicate, passing between the lower cornu of the sacrum, and the upper border of the coccyx, communicates within the bone with the descending branch of the fifth, and terminates by passing along the border of the coccyx in the substance of the sacro-sciatic ligament to become cutaneous. Some filaments are given off from it which supply the coccygæus; others perforate the ligament, and are lost in the substance of the glutæus maximus.

The Sacral Plexus (sciatic) is formed by the lumbo-sacral nerve and the four upper anterior branches of the sacral nerves, principally, however, by the convergence of the three upper: the fourth sacral nerve sending merely a small filament of communication. The branches that contribute to its formation enter it at once, at a more or less acute angle, without any complex subdivision, as usually occurs in other plexuses. It has a well marked triangular figure, the apex being indicated by the line of convergence of the different trunks: the base by the trunks as they issue from the sacral foramina. It rests upon the pyriformis muscle, the internal iliac vessels separating it from the pelvic viscera, being however in immediate relation with a layer of pelvic fascia. Before terminating in the great sciatic nerve, the plexus gives off a series of anterior and posterior branches. Of the former are observed, a nerve for the obturator internus, and the internal pudic: of the latter, the superior glutæal, inferior glutæal, nerves for the pyriformis, gemelli, and quadratus femoris.

The nerve for the obturator internus takes its origin from the upper and outer part of the plexus, being derived from the lumbo-sacral and first sacral. It passes behind the spine of the ischium, and the lesser sacro-sciatic ligament, reenters the pelvis at the lesser sciatic notch, and is distributed by three or four branches within the inner aspect of the muscle.

The internal pudic nerve, arising from the lower part of the plexus, and generally derived from the third and fourth nerves, passes behind the spine of the ischium, internal to the pudic artery, in company with the preceding, and then enters the ischio-rectal fossa, where it divides into a superior and inferior branch.

The superior branch (*the dorsal nerve of the penis*) ascends in company with the internal pudic artery, but above it, between the obturator internus and the levator ani, to pass between the two layers of the triangular ligament: perforating the anterior layer immediately under the pubic arch it gains the dorsum of the penis, in which situation it is placed in the fold of the suspensary ligament, and inclines inwards to the median line. Having given off one or more external branches, which run superficially as long and slender filaments along the upper and outer part of the penis, supply the corpora cavernosa and their integument, and are conducted as far as the prepuce, the nerve continues its forward direction. It passes to the side of the median line, sends numerous filaments to the skin; communicating branches to the nerve of the opposite side; and some to accompany the dorsal vein of the penis; and at the root of the glans penis, penetrates deeply between it and the corpus cavernosum, and terminates by sending numerous filaments throughout its substance.

The inferior branch (Perinæal nerve — superficial perinæal) perforates the obturator fascia at the inner and anterior part of the tuberosity of the ischium, and divides into two branches, an anterior and superior, having previously given off a posterior branch, named by Cruveilhier the *external perinæal*, which passes through the obturator fascia behind the tuberosity of the ischium. It runs in company with, but external to, the anterior branch, superficial to the crus of the penis, and terminates by supplying the lower and anterior part of the scrotum where it gives off filaments on the inside to unite with some from the anterior branch, on the outside to communicate with the long inferior pudendal branch of the lesser sciatic. The anterior branch passes in the interval between the accelerator urinæ and the erector penis, internal to the preceding, and inclines a little forwards and inwards, and ends in a series of long filaments, which communicate laterally with the external perinæal, and send branches to the middle of the lower and anterior part of the skin of the scrotum, some of them being conducted along the skin at the lower aspect of the penis as far as the prepuce. The superior branch soon divides into a series of muscular branches, after having passed above the transversalis perinæi muscle. Some are sent inwards to the external sphincter, levator ani, and accelerator urinæ: others to the erector penis; the termination of the nerve being represented by a small branch, which passes into the substance of the bulbous portion of the urethra.

The pudic nerve not unfrequently gives off *the inferior hæmorrhoidal* (anal), which passes along its inner side, is directed through the obturator fascia to the ischio-rectal space which it traverses to the side of the rectum, and at the upper border of the external sphincter divides into a series of filaments, the anterior of which communicate with the superior branch of the perinæal, and supply the front of the sphincter and the skin over it. The middle and posterior series supply the sides and back part of the sphincter. Some filaments are given off externally, which pass over the great trochanter, and communicate with the long inferior pudendal nerve. The skin about the anus is also freely supplied.

The inferior hæmorrhoidal, when not a branch of the pudic, is given off from the sacral plexus.

The superior glutæal nerve is derived either from the lumbo-sacral nerve only, or from two distinct roots, the one from it and the other from the back part of the first sacral nerve. The former source of origin usually obtains; and in the latter the root from the sacral nerve is not more than half as long as that from the lumbo-sacral. It passes out as a single trunk at the upper and fore part of the border of the sacro-sciatic notch, in front, and above the pyriformis, and divides into *a superior and inferior branch.*

The superior branch takes the course of the superficial trunk of the corresponding artery, courses along the convex border of the glutæus minimus, and supplies principally the upper and back part of the glutæus medius. The *inferior branch* is directed downwards, forwards, and outwards between the two glutæi, and, after a short course, divides into a superficial branch, supplying the upper and anterior part of the glutæus medius; and a deep branch running across the glutæus minimus, supplying it and the medius, and terminating near the great trochanter, by entering the substance of the tensor vaginæ femoris, at the lower, inner, and back part of its sheath.

The inferior glutæal nerve (lesser sciatic) arises from the back part of the sacral plexus by one or more roots. It emerges from the pelvis at the lower and anterior part of the great sacro-sciatic notch, either as a single, or as two, or three, trunks, below the pyriformis, and about a quarter of an inch behind and internal to the great sciatic. It is directed between the tuberosity of the ischium, and the great trochanter, but nearer the former, over the back and inner part of the gemelli, and divides into *muscular and cutaneous branches. The muscular branches* are long and numerous, being destined to supply the glutæus maximus. One series are directed outwards, upwards, and forwards, and, entering its anterior surface, ramify through the substance of the muscle, as far as its upper and anterior part. The other series are directed downwards, backwards, and outwards, over the tuberosity of the ischium, and supply the lower and back part of the muscle.

The inferior glutæal having emerged from beneath the lower border of the glutæus maximus, divides into its two terminal branches, *perinæal cutaneous, and cutaneous branch to the thigh and upper part of the leg. The perinæal cutaneous nerve* is reflected upon the lower border of the glutæus maximus, and describes a curve, the concavity of which looks towards the sacrum. It soon divides into an external large branch, supplying the skin in the glutæal region, and an internal small branch (the long inferior pudendal of Sœmmering), which passes in a curved manner beneath the tuberosity of the ischium. It is then directed beneath the fascia of the upper and inner part of the thigh, running parallel to the ascending ramus of the ischium, and at or near the junction of the latter with the descending ramus of the pubis, perforates the fascia, and becomes cutaneous, supplying the skin in the perinæum ; it anastomoses either with the superficial perinæal, or the external perinæal nerve, and sends terminal branches to supply the inner and outer portions of the scrotum, and the lower part of the skin of the penis.

The cutaneous branch to the back of the thigh and upper part of the leg. — The continuation of the trunk of the inferior glutæal is situated anterior and external to the above-named branches. It passes obliquely over the inner and back part of the biceps muscles, and, a little above the middle of the thigh, ordinarily divides into two branches. The small external branch passes downwards, forwards, and outwards to the upper part of the lower third of the thigh, in which situation it anastomoses with the external cutaneous nerve of the lumbar plexus. The large internal branch runs down a little to the inside of the median line of the thigh to the skin in the poplitæal region, where it divides into external terminal filaments, supplying the skin over the outer and back part of the tibia and fibula, and internal filaments, some of which go to the skin at the inner part of the poplitæal region, others very small, accompanying and surrounding the external saphæna vein, communicate below the middle of the leg with filaments given off from the external saphænus nerve.

The nerve for the pyriformis passes below the level of the superior glutæal nerve, from the middle of the back part of the plexus, generally taking its origin from the third sacral nerve. It is distributed to the anterior surface of the muscle.

The nerves for the gemelli and quadratus femoris pass from the plexus along the lower part of the pyriformis, close to the os innominatum, to the anterior surface of the muscles. That for the quadratus femoris gives off a few branches to the capsular ligament, one of which enters the articulation, and usually sends off the nerve which supplies the inferior gemellus. This nerve comes off frequently from the upper part of the great sciatic.

The great sciatic nerve (the sciatic, ischiatic, femoro-poplitæal), the largest nerve in the body, is formed by the convergence of a branch of the fourth lumbar, the lumbo-sacral, and the three or four upper sacral nerves ; represents the termination of the sacral plexus, and is destined to supply the muscles at the back part of the thigh, and the muscles and integuments of the leg and foot. It escapes from the pelvis, from beneath the lower border of the pyriformis, as a flattened ribbon-shaped nerve, about half an inch broad, soon becomes rounded, and continuing its course from between the great trochanter and tuberosity of the ischium, descends with a slight inclination outwards to the back part of the thigh, a little to the outside of the median line, as far as, or somewhat above, the level of the upper angle of the poplitæal space, where it divides into terminal branches, the peronæal and posterior tibial. This division occasionally takes place within the pelvis, in which instances the outer division passes either between the lower fascicles of the pyriformis or above the muscle, the inner beneath the lower edge of the muscle. In some instances it takes place while the nerve is placed between the trochanter and tuberosity: in others, again, the two trunks are distinct as far as this situation, where they again unite, and subsequently divide in the poplitæal space. In the upper part of its course the nerve is rather deeply seated, being covered over by the glutæus maximus, and having behind and internal to it the branches of the inferior glutæal nerve. At the lower border of the tendon of the glutæus maximus it is crossed by the long head of the biceps, and in the remainder of its course is covered only by the fascia.

It is in relation in front with the two gemelli and obturator internus, the quadratus femoris and adductor magnus. Behind these muscles it passes successively, from above downwards, is in close contact with the superior, and separated from the adductor magnus by a quantity of fat and cellular membrane. The branches given off from the sciatic nerve are muscular and articular. The muscular branches come away above the middle of the thigh, with the occasional exception of that for the short head of the biceps, which arises near the middle.

There are several *branches for the long head of the biceps*, some of which ascend to be distributed to the muscle at its origin; others descend for some distance, and enter its anterior surface.

The nerve for the semi-tendinous is a long delicate filament, which usually passes down to the lower third of the thigh before it enters its surface.

The semi-membranosus generally receives *two or more branches:* and from the lower is not unfrequently derived a branch for the adductor magnus, which also receives a branch from the main trunk.

The articular nerve is usually given about the middle; but as this nerve, in the majority of instances, is derived from the peronæal, it will be described with that nerve.

The peronæal nerve (external poplitæal — external poplitæal-sciatic) is more superficial, and not much more than a third the size of the posterior tibial. It is directed downwards and outwards along the inner edge of the biceps muscle, behind the outer condyle of the femur, the outer head of the gastrocnemius, and the outer and back part of the head of the tibia, to below the head of the fibula, where it divides into four branches, *the anterior tibial,* and *musculo-cutaneous,* the former being larger than the latter.

The peronæal nerve, during this course, gives off *superficial cutaneous branches, and occasionally deep articular:* the former being represented by the *peronæal cutaneous and peronæal saphænus,* the latter *by the superior and inferior external articular.*

The peronæal cutaneous proceeds from the back part of the nerve, generally an inch or two after its commencement. Having passed superficially with the trunk as far as its termination, and having supplied the integuments in its course, it gives branches on the one hand to the integuments immediately on the outside of the external saphænus, and on the other over the upper part of the peronæus longus, the middle terminal filaments extending below the middle of the leg, and communicating with cutaneous branches from the external saphænus.

The peronæal saphænus (communicans fibulæ — communicating saphænus) usually taking its origin above and to the inside of the peronæal cutaneous, is directed downwards and inwards beneath the skin, and communicates with a corresponding branch from the posterior tibial to form the external saphænus. This communication is very variable as to situation, usually taking place below the middle of the leg, where it perforates the fascia, occasionally, however, in the lower part of the poplitæal space in front of the fascia. The nerve now and then runs quite distinct from its corresponding branch, which consequently in these instances entirely constitutes the external saphænus. It is either very small, terminating about the middle of the leg, or divides opposite the lower part of the tendo Achillis into branches which pass over the lower part of the peronæus longus to the skin of the external malleolus, where they communicate with small descending branches from the musculo-cutaneous; and into those which supply the skin at the lower and outer part of the heel, communicating in the interval between the heel and malleolus with branches from the external saphænus.

The deep articular branches are external and internal, the one arising above the other. They are thus described by Mr. Ellis*: — "*The superior external articular nerve,* arising either from the trunk of the sciatic or the external poplitæal in the case of a high division of the sciatic, is a long slender nerve, which descends deeply into the poplitæal space, under cover of the biceps muscle, nearly as low as to the outer condyle, then passes from the space beneath the tendon of the biceps, reaches the superior articular artery, which it accompanies to the front of the joint, and supplies the synovial membrane of the articulation.

The inferior external articular, more frequently a branch of the external poplitæal than of the sciatic, is also a long nerve close to the biceps, and has the same direction as the preceding; but it extends lower down, passing beneath the tendon of the biceps, and below the condyle of the femur, to the artery of the same name, and it divides on the outer side of the articulation into many branches that extend forwards, perforate the capsules, and supply the synovial membrane.

The anterior tibial nerve (interosseous nerve), rather larger than the musculo-cutaneous, passes from beneath the extensor communis digitorum, having previously perforated the deep surface of the peronæus longus, to the interosseous membrane, which it crosses obliquely downwards, forwards, and inwards; and a little below the middle of the leg is placed in front of the corresponding artery. It continues to accompany the vessel beneath the annular ligament, passing first to the inside of it, then to the outside, and again to its inside, while behind the annular ligament it divides into an internal and external terminal branch. The nerve in this course is placed first between the tibialis anticus and extensor communis digitorum; then between the former and the extensor proprius pollicis, and lastly between the extensor pollicis and the extensor communis digitorum. In its course from the leg to the ankle the anterior tibial gives off branches to the different muscles between which it passes; and also one or two delicate satellite filaments to the anterior tibial vessels.

The terminal branches are both rather deeply seated. The *internal deep branch,* the continuation of the trunk in reference to direction, but not to size, being smaller than the external, passes beneath the dorsal artery of the foot and the tendon of the extensor brevis destined for the great toe, gives filaments to supply the inner part of this muscle, and reaches the first interosseous space, sending a few twigs to the first interosseous muscle. At the anterior part of this space it communicates with the musculo-cutaneous, and terminates by dividing into two branches destined for the opposed sides of the first and second toes.

The external deep branch passes obliquely

* Ellis's Demonstrations of Anatomy, p. 675.

outwards beneath the exterior brevis, supplies this muscle, and gives off from its anterior part several delicate filaments, which running close to the tarsus reach the three outer interosseous spaces, and expand in the substance of the interosseous muscles.

The musculo-cutaneous nerve (the external peronæal), commencing its course below and behind the anterior tibial, and running more superficial and external than it, is directed, first obliquely then vertically downwards in the substance of the peronæus longus; it is then situated behind the fascia, and at a variable distance from the ankle, generally at the lower third, perforates the fascia, between the extensor communis, and peronæus tertius. Subcutaneous in the remainder of its extent, it follows the course of the extensor communis, and after running for a greater or less distance parallel to it, divides into an internal and external branch which diverge considerably from each other. This bifurcation is subject to variation, taking place sometimes while the nerve is situated behind the fascia, at others over or very near the annular ligament, and occasionally the two divisions reunite over the annular ligament, and form an irregular oval space between them. While passing deeply between the muscles of the leg this nerve sends two filaments to the peronæus longus, the inferior of which, given off about the upper fourth of the leg, can be traced running in the subtance of the muscle, to within two or three inches of the ankle. The upper part of the peronæus brevis also receives a small branch. Shortly after perforating the fascia, the musculo-cutaneous sends off its *malleolar branches* directed downwards and outwards to the skin over the outer ankle, and anastomosing with cutaneous branches either from the external saphænus, or the termination of the peronæal cutaneous.

The internal terminal branch, passing over the annular ligament giving a few branches to it, and some to communicate with the internal saphænus and anterior tibial, is directed along the inner border of the foot to the inside of the great toe as far as its extremity. *The external branch*, having passed over the annular ligament, divides into three branches which are directed along the three outer interosseous spaces, and near their anterior extremities, each branch again subdivides into two filaments supplying the opposed sides of the four outer toes, the most external filament anastomosing with the external saphænus. Both terminal branches, in their course from the annular ligament to the toes, send off numerous filaments to the skin on the dorsum of the foot. Such is the usual distribution of the musculo-cutaneous nerve; but frequently the outer branch does not supply the inner side of the little toe, and occasionally gives filaments only to the opposed sides of the second and third toes. In these instances an extension of the external saphænus nerves compensates for the deficiency.

The tibial nerve (tibial-sciatic, internal poplitæal) much larger than the peronæal or external poplitæal, is in a direct line with the sciatic nerve. It passes through the centre of the poplitæal space, rather nearer the semimembranous than the biceps, then between the two heads of the gastrocnemius to the lower border of the poplitæus. It perforates the tendinous arch of the solæus, reaches the front of that muscle, and passes down the leg between it on the one hand and the deep-seated muscles on the other. At the lower third of the leg it runs from beneath the inner border of the solæus, and continues its terminal superficial course, anterior and internal to the tendo Achillis, as far as the lower extremity of the tibia, and, on a level with the base of the external malleolus, divides into the internal and external plantar. In the upper part of the poplitæal span, the tibial nerve is superficial and external to the poplitæal vessels in the middle immediately behind, and at the lower part is placed internal to them. This last relation the nerve holds as far as the lower third of the leg, when it crosses the posterior tibial artery again to its outer side. It continues very gradually to separate from the vessel; so that in the interval between the heel and malleolus the nerve is a quarter of an inch nearer the os calcis than the vessel. The branches given off from the tibial are *muscular, articular, and cutaneous.*

The majority of the muscular branches arise from the posterior part of the trunk, and we observe, first, two branches for the two heads of the gastrocnemius entering their anterior surface. The inner branch arises frequently from a trunk common to it and the tibial saphænus; the outer, from a trunk common to it and a large branch for the solæus, which enters, usually, the posterior surface of that muscle. When the outer branch is small, one or two others are given off lower down, to enter its anterior aspect. *The small branch for the plantaris* is derived, in the majority of instances, from the trunk of the tibial; but sometimes from the inferior internal articular nerve.

The nerve for the poplitæus, given off opposite the knee-joint, is directed forwards to the poplitæal vessels, descends external to them, and terminates at the lower border of the muscle by entering its substance.

The nerve to the tibialis posticus comes off from the above, descends along the back of the muscle, gives numerous filaments to it, and terminates by entering below the middle.

The nerve for the flexor communis digitorum and the longus pollicis take their origin together somewhat below the preceding; that for the latter muscle being the larger, and descending to within a short distance of the ankle joint, in company with the fibular artery. The articular branches are three in number, and correspond with the internal and anterior articular branches of the poplitæal artery.

" *The superior internal articular*, very small, arises above the articulation, descends on the outer side of the poplitæal vessels, passes beneath them, and runs with its artery to the front of the femur and inner part of the articulation; this is the least constant of the branches. *The inferior internal articular*, the largest of the nerves to the joint, arises rather above the articulation, descends to it, lying external to the vessels, is then directed inwards, beneath the poplitæal vessels, and meets with the artery of the same name; it now lies on the poplitæus, covered by the fascia, passes beneath the internal lateral ligament, winds round the head of the tibia, perforates the capsule, and supplies the synovial membrane. This branch gives, occasionally, some filaments to the posterior part of the articulation. The last articular branch is the *posterior* or *azygos*, which is given off opposite the joint, or from the inferior internal nerve: it perforates the posterior ligament, and is distributed to the articulation."* We have observed this inferior articular nerve give off, occasionally, muscular filaments to the plantaris, and upper part of the poplitæus.

The cutaneous branch is named the *tibial saphœnus* (external saphænus—communicating saphænus—communicans tibiæ), and takes its origin from the back part of the trunk external to the muscular branches. It inclines a little to the outside of the middle of the poplitæal space, under the fascia, but superficial to the gastrocnemius, along the posterior surface of which it passes till it perforates the fascia at a variable distance from the ankle, and receives the corresponding branch from the peronæal saphænus. It is then directed, under the name of the *external saphœnus*, along the outer part of the tendo Achillis to the outer and back part of the external ankle, where it divides into its terminal branches. In the first part of its course it lies to the inside of the external saphæna vein. Near the lower angle of the poplitæal span it passes in front of the vein to get to its outside, continues external to it as far as about an inch above the outer ankle, and again passes in front of it to its inside.

The tibial saphænus gives off no branch till it becomes external saphænus, and internal and external cutaneous branches arise from it. The internal supply the outer and back part of the leg: and a *superior and inferior calcaneal branch* are generally observed. The superior is directed over the tendo Achillis, supplies the skin at the inner and back part of the heel, and communicates with filaments from the external plantar: the inferior passes along the outer border of the tendo Achillis to the skin at the outer and lower part of the heel. The outer cutaneous run downwards and forwards over the tendon of the peronæus longus, as far as the malleolus externus, communicating above with descending filaments of the peronæal cutaneous; and below with the malleolar filaments of the musculo cutaneous. Independent of these, cutaneous filaments and a few delicate nerves are given off, which accompany the saphæna vein.

The terminal branches are composed of a series of cutaneous branches to the back part of the ankle, heel, and back part of the outer edge of the foot, and a long nerve, the continuation of the trunk directed along the outer edge of the foot to supply the outer margin of the little toe, communicating previously with the musculo-cutaneous.

The termination of the tibial saphænus nerve is subject to considerable variation, both as to size and distribution. It occasionally forms no connection with the peronæal saphænus, and then is very large. When united with the peronæal saphænus, so as to form the external saphænus, its terminal branch not unfrequently divides into two; the one division for the opposed edges of the fourth and fifth toe; the other for the outer edge of the latter. We have observed the saphænus nerve supplying also the opposed edges of the third and fourth toes, whilst the musculo-cutaneous in this instance supplied merely the inner edge of the great toe and the opposed margins of the second and third toes.

The tibial nerve, before dividing into the internal and external plantar, gives off, a little above the ankle, an *internal calcaneal branch*, which in a high division of the nerve comes away from the external plantar. Having supplied the skin at the inner aspect of the heel, it winds beneath the inferior surface of the os calcis, and communicates with the calcaneous branch of the external saphænus.

The internal plantar nerve, larger than the external and analogous to the median nerve in the hand, passes behind the internal malleolus superficial to and distinct from the tendons of the tibialis posticus, and in front of the posterior tibial vessels. It then runs above the abductor pollicis, and is directed in the intermuscular septum, between it and the flexor brevis digitorum. Having perforated this, it appears between the two muscles, and divides into internal and external branch es

The internal branch is smaller than the external, passes from without inwards over the tendon of the long flexor of the toe to the inner side of the metatarsal bone, gives filaments to the abductor pollicis, flexor brevis, and the skin, and terminates at the inner side of the toe, supplying in its course filaments to the articulations, and when it reaches the last phalanx, a small cutaneous branch to the dorsum.

The external branch divides after a course of about an inch or two. The internal division, as it is directed along the first interosseous space, gives off in its course filaments to the first interosseous and lumbricalis, and at the anterior part of this space divides into two twigs for the opposed sides of the great and second toe. The external division, after a very short course, divides into two branches: the *internal* crosses obliquely the second interosseous space, gives filaments to the second lumbricalis, and bifurcates at its anterior extremity for the supply of the opposed sides of the second and third toes: the *external* crosses obliquely to the third interosseous space, and like the preceding divides at its anterior extremity into two twigs for the

* Ellis's Demonstrations of Anatomy, p. 676.

opposed sides of the third and ourth toes, having previously communicated with the external plantar.

These different divisions of the internal plantar nerve give off, in their course, filaments to those portions of the cuticle with which they are in relation; and also small twigs for the metatarso-phalangeal and phalangeal articulations, and muscular branches to the flexor digitorum brevis, over the tendons of which the different divisions of the external portion of the nerve are obliquely and superficially directed.

The external plantar nerve, smaller than the internal, is directed forwards and outwards between the musculus accessorius and flexor digitorum brevis, giving filaments to either, and, having reached the inner border of the abductor minimi digiti, which muscle it supplies, divides into a deep and superficial branch.

The deep branch passes from between the first and second layer of muscles to place itself between the latter and the third, passing in company with the exterual plantar artery. It describes a curve, the concavity of which looks towards the heel and inner malleolus. Filaments are sent off for the two outer lumbricales, for the transversalis pedis, the adductor pollicis, the interossei, and the tarsal and metatarsal articulations.

The superficial branch passes obliquely forwards and outwards between the flexor brevis digitorum and abductor minimi digiti, to both of which it gives filaments, and soon divides into an external and internal branch.

The external branch reaches the outer border of the foot, and terminates at the extremity of the outer aspect of the little toe; giving filaments to the flexor brevis minimi digiti and the articulations. The internal, larger, communicates with the most external division of the internal plantar, and bifurcates at the extremity of the fourth interosseous space, for the supply of the contiguous sides of the fourth and fifth toes. The divisions of the superficial branch of the external plantar nerve, like those of the internal, supply the portions of the integument with which they are in relation, as also the articulations over which they pass.

The internal and external plantar nerves are, in reference to size, directly the reverse of the corresponding arteries: the former giving off seven filaments for the supply of the three inner toes, and half of the fourth; and being analogous in its distribution to the median in the hand: the latter giving off only three filaments for the fifth and half of the fourth toe, and corresponding with the distribution of the termination of the ulnar nerve.

(*Nathaniel Ward.*)

SPLEEN. (*Lien seu Splen*, Lat.; Σπλήν, Gr.; *die Milz*, Germ.; *la Rate*, Fr.) Normal anatomy. The spleen is a single so-called "vascular gland," which is attached to the cardiac extremity of the stomach, and appears to possess some intimate connection with the renovation of the blood.

Situation and form. — The spleen has a roundish elongated form, or almost the shape of half an egg, and lies in the left hypochondriac region. We recognise on it two surfaces, two borders, and two extremities. The *outer surface* (*superficies externa seu convexa*) is completely free and smooth, and often exhibits a more or less deep, long, and oblique incision: it looks outwards, upwards, and backwards; and is in contact with the left costal portion of the diaphragm, corresponding to the tenth and eleventh ribs. The *inner surface* (*superficies interna seu concava*) is directed inwards and forwards; is for the most part slightly concave, and presents, in a prolonged elevation which occupies its middle, a vertical furrow, the fissure for the vessels, or *hilus lienalis*, which contains many holes and depressions, through which pass the nerves and vessels to and from the spleen. This fissure separates the concave surface into an anterior and larger, and a posterior and smaller portion; and it is connected by the broad, but short gastro-splenic omentum (*ligamentum gastro-lienale*), with the fundus of the stomach, to which the remainder of the concave surface is opposed. The *upper extremity* or head of the spleen (*caput lienis*), is the thicker and more obtuse of the two; it occupies the elevated hinder part of the eighth rib, and is connected by a suspensory ligament (*ligamentum phrenico-lienale seu suspensiorum*) with the diaphragm. The *lower extremity* or *cauda lienis*, is thinner and more pointed, and is directed downwards and forwards. The *anterior border* (*margo anterior*) is the thinner and sharper, and is free. The *posterior border* (*margo obtusus*) is thick and rounded, and is in contact with the lumbar portion of the diaphragm, and the anterior surface of the left suprarenal capsule. The spleen is thus least moveable, where it is limited by the diaphragm; but much more so at the site of its attachment to the stomach. But its situation changes with the variable positions of the diaphragm and stomach: thus, on the one hand, it descends and rises in the states of in- and expiration respectively; and, on the other hand, becomes more superficial or deeper, according as the stomach is empty or full.

Varieties of the spleen. — It is not uncommon to find the anterior border of the spleen, presenting one or more separate deep fissures. Also supplementary spleens (*lienculi, seu lienes succenturiati*) are now and then observed: according to Rosenmüller and Giesker, more frequently in the Southern than in the Northern Germans. These are situated in the gastrosplenic ligament, and rarely in the great omentum (Morgagni, Huschke); they are red, of the ordinary splenic structure, and of a size which varies from a linseed to a walnut. They are generally one or two in number, less frequently four or seven, and in a misdeveloped fœtus have even amounted to twenty-three.

The *size and weight* of the spleen experience great variation, not only in different individuals, but even in one and the same person:

of this more will be said hereafter. On an average, its length is from 4 to $5\frac{1}{2}$ inches * ; its thickness from 1 to $1\frac{1}{2}$ inches ; and its breadth, from the anterior to the posterior border, 3 to 4 inches. According to Krause, its cubic contents range between $9\frac{3}{4}$ and 15 inches, with an average of 12. Its absolute weight varies from 6 to 15 oz., according to Soemmering ; from $7\frac{1}{2}$ to $10\frac{1}{2}$, according to Krause ; and it has a medium of about 8 oz. According to J. Reid †, between the twentieth and sixtieth years, it ranges from 6 to 10 oz. in the male, and from 3 oz. $13\frac{1}{2}$ dr. to 9 oz. 10 dr. in the female. Krause also states, that its specific gravity varies from 1.0579 to 1.0625, with an average of 1.0606.

The *consistence* of the spleen is not very great : its parenchyma is soft and doughy, readily yielding to the pressure of the finger. It is not unfrequently torn by mechanical injury during life ; indeed, more easily than any other glandular organ, especially if it be over-distended with blood at the time; but, under the opposite circumstances, it is much less disposed to give way. The colour of the spleen is bluish red, during life greyish violet, and the parenchyma is of a dark dusky red.

Structure. — In the spleen we first distinguish the *coverings* or *involucra*, and the *parenchyma* or proper spleen-substance. The first consists of the serous and the fibrous membrane. The latter is composed of a framework of reticulated fibres firmly connected together, constituting the so-called trabecular tissue (*trabeculæ lienis*) ; and, beside this, of the red spleen-substance, the splenic corpuscles, and vessels and nerves, together with sheaths which arise from the fibrous coat.

1. The *serous membrane* (*tunica serosa*) is a part of the peritoneum. It accurately covers the outer surface of the spleen as a smooth membrane, with the exception of its hilus only, where it takes the form of two folds which convey the vessels of the organ, constituting the gastro-splenic ligament, and passing off to the stomach, where they become continuous with its serous covering. When the ligament uniting the spleen to the diaphragm exists, the membrane is similarly continuous with the peritoneum covering this muscle. The serous membrane is a thin, moderately strong, whitish membrane, which is intimately connected with the fibrous coat ; although in particular places, and especially after previous maceration, the two may be separated from each other. In respect of its microscopical structure, it scarcely differs at all from other parts of the visceral layer of the peritoneum; thus it consists of an outer and single layer of polygonal pavement epithelium, and of an inner layer of white fibrous tissue, in which meshes of fine fibre of yellow tissue are present in no very considerable quantity.

In mammalia, *e. g.* in the sheep, ox, &c., as was remarked by Malpighi, the serous membrane is easily separated entire. But in man this is not the case, and hence Haller and others have supposed that only one membrane is present. But microscopical research proves the opinion to be erroneous ; and pathological anatomy confirms this statement, by showing that the outer part of the coat of the spleen shares in the diseases of the peritoneum. In animals numerous vessels are seen in the serous membrane, and a very dense network of stronger and thicker fibres of yellow tissue is present.

2. The *fibrous coat* (*tunica fibrosa, albuginea, sive propria*) is in man a moderately delicate semi-transparent, but firm, membrane, which encloses the parenchyma of the spleen on every side, so as to include it in a kind of sac. Its outer surface is even, and in man is intimately united with the serous covering, with the single exception of the hilus, where the two membranes diverge, and are separated from each other by vessels, nerves, and a loose areolar tissue. The inner surface bounds the parenchyma of the organ, and, with the exception of very numerous solid processes which come off from it, is limited by the trabecular tissue. At the hilus of the spleen it sinks into the interior of the organ in the shape of tubes (*vaginæ vasorum*), which ensheath the entering and emerging vessels, and are continued on these throughout the whole parenchyma. The fibrous coat, in the human subject, is composed of white fibrous tissue, mixed with elastic or yellow fibres. The former of these, as in other fibrous membranes, consists of bands, which take a parallel course, but do not form distinct bundles ; and the latter are united in a very dense and irregular network. Duvernoy and Stukely have described muscular fibres in this tunic ; but, according to my researches, they certainly are not present in the human subject, although I have found them existing in some of the mammalia, and most visibly in the dog and pig. They are unstriped muscles, the elements of which, the elongated cells or "fibre cells" (*fig.* 522.) which I have described *, are deposited in considerable quantity amongst the elastic network and white fibrous tissue previously mentioned.

Fig. 522.

Muscular fibre-cell from the tunica propria of the spleen of the Dog, magnified 350 diameters. *a*, nucleus of the same.

In addition to these two animals I have also found the muscular structure in the cat, the ass, and the Dicotyles

* In this and the following measurements the German inch and line have been retained.

† London and Edinburgh Monthly Journal, April, 1843.

* Zeitschrift für wissenschaftliche Zoologie, von v. Siebold und Kölliker, Leipzig, bei Engelmann, Jahrgang, 1848, Heft 1.

torquatus, while it was absent in the rabbit, horse, ox, hedgehog, guineapig, and bat. The elastic fibres of this tunic are for the most part much stronger than in man.

Their peculiar vessels and nerves I have never witnessed.

3. The *trabecular tissue*, (*trabeculæ lienis*, *balks*, or *joists* of the spleen), consists of white, shining, flat or cylindrical fibres, which arise in great numbers from the inner surface of the fibrous coat; and, in smaller quantity, from the exterior surface of the sheaths of the vessels. These are so connected with similar fibres in the interior of the spleen as to constitute a network which extends throughout the whole organ. Between the fibres of this net exist a great number of spaces which are connected with each other, and are occupied by the red spleen-substance and splenic corpuscles ; and which, although very irregular in respect of their form, and, as regards their size, of the most variable dimensions, have yet a considerable resemblance to each other. The older anatomists regarded these spaces as regular and uniform cavities provided with a special membrane. But this last structure nowhere exists, as may be verified in a spleen in which, after short maceration, the pulp has been removed from these spaces by washing. Such a preparation will also afford the best means of studying the mode of connection of the fibres, and in this manner it may be seen that, although they are of very different diameters, yet the finer fibres are not everywhere given off from the thicker ones. This is especially shown by the fact, that fibres of the most different diameters are intimately connected together at all points. Where four, five, or more of these joists meet, there generally occurs a knot of a flattened cylindrical form, which is not unlike that of a nerve-ganglion. Such knots are more frequently found towards the outer surface of the organ, since the cross-beams are more numerous here than in the interior. In this latter part, namely in the neighbourhood of the great vessels, the numerous ramifications of these tubes themselves serve as points of support to the pulp, and consequently render the joists less necessary.

The structure of the trabecular tissue of the human spleen completely corresponds with that of the fibrous tunic, since it consists of white fibrous tissue and the yellow fibres. The former of these two structures exhibits parallel fibrillæ, which run without exception in the direction of the long axis of the partition or joist, and rarely unite into individual bundles. The latter consists of somewhat finer and stronger yellow fibres, which anastomose with each other ; their maximum diameter is 1,1000th of a line: the greater number of them lie between the bundles of white fibrous tissue, and are easily recognised by their irregular course and manifold curves. Many anatomists, with Malpighi, had spoken of muscular fibres in the partitions of the spleen, although none had succeeded in demonstrating them, either with the scalpel or microscope, or chemically. But in 1846 I discovered them with the aid of the microscope, in the spleen of the pig.* Here they exist both in the finest and largest of the partitions, but they are not isolated, being connected with the finer reticulations of the yellow fibres (*fig.* 523.). In the larger partitions which are

Fig. 523.

a, muscular fibre-cells with a projecting extremity or not isolated; *b*, nuclei of the same; *c*, elastic fibres.

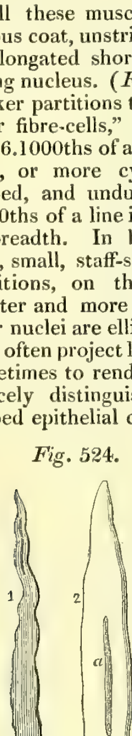
visible to the naked eye, the muscular and elastic fibres are present in pretty nearly equal quantities, consequently these parts are to be regarded as alike elastic and contractile. But in the smallest and microscopic cross-beams the muscular fibres predominate, and often they appear to be even unmixed with elastic fibres. In these parts the quantity of white fibrous tissue is still smaller than that of the yellow ; indeed, in this animal it is but very sparingly present in the larger partitions. The direction of the fibres above-named is always longitudinal or parallel to the long axis of the joist, never transverse. In similar extent and quantity, and with a like connection to the elastic tissue, I have found muscular fibre in the dog, the ass, the cat, the Dicotyles torquatus, the sheep, rabbit, horse, hedgehog, guineapig, and bat. In the ox, on the contrary, it exists only in the finer and microscopic partitions, where it is present in very considerable quantity and in remarkable distinctness. The remainder of the trabecular tissue consists only of yellow fibre in union

* Mittheilungen der naturforschenden Gesell schaft in Zurich, 1847, S. 120.

with some white fibrous tissue. As to the lower vertebrata, I have examined a great number of them with respect to this muscular structure, and have found that the smallness of the spleen in many of them offers a great obstacle to observation; yet I believe I have verified that the spleens of the pigeon, sparrow, blindworm, tench (*tinca chrysitis*), and trout, contain muscular fibres. So, also, my friend Professor Ecker, of Basle, has orally communicated to me that he has found very distinct muscular fibre in the spleens of the ray and shark.

All these muscles are, like those of the fibrous coat, unstriped; their elements consist of elongated shortish fibres, each possessing a long nucleus. (*Fig.* 523. *a*, *Fig.* 524.) In the thicker partitions there are what I call "muscular fibre-cells," either stiff, pale, flat, from 4 to 6.1000ths of a line broad, and 2 to 3.100ths long, or more cylindrical, darker, spindle-shaped, and undulating, varying from 2 to 5.100ths of a line in length, and 3 to 4.1000ths in breadth. In both cases they have long, neat, small, staff-shaped, nuclei. In the finer partitions, on the contrary, appear many shorter and more spindle-shaped fibre-cells; their nuclei are elliptical or even spherical, and they often project laterally from the fibres, so as sometimes to render these muscular elements scarcely distinguishable from the spindle-shaped epithelial cells of the splenic arteries.

Fig. 524.



Muscular fibre-cells from the trabeculæ of the Pig, magnified 350 *diameters.*

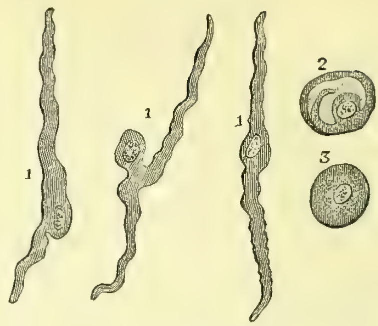
1, without acetic acid; 2, with acetic acid; *a*, nucleus.

The muscular elements just described are seen in the best and plainest manner in the pig and dog; but they are also readily verified in the horse, ox, ass, sheep, and cat, in all of which they may frequently be isolated. In the other mammals previously named, and in the rest of the vertebrata, they are less easily recognised, and are scarcely susceptible of isolation; but they can always be partially uncovered, and in any case may be demonstrated by the application of acetic acid, which displays their characteristic nuclei.

As regards the human subject, I find that in the partitions which are visible by the naked eye, no trace of unstriped muscular fibre is present; and they probably consist entirely of yellow and white fibrous tissue. In the finer partitions, on the contrary, elements occur to which one may perchance ascribe a muscular character. They are the same short fibres of a peculiar kind (*fig.* 525. 1.), which Günsburg* has

* Pathologische Gewebelehre, Band. i. S. 81.

Fig. 525.



Peculiar structures from the human spleen, magnified 350 *diameters.*

1, spindle-shaped fibres with a nucleus; 2, a cell, which contains such a fibre; 3, a similar cell, without a fibre.

erroneously regarded as epithelial cells of the splenic veins; otherwise they have hitherto remained altogether unnoticed. They are characterised by their roundish or elongated oval nucleus, which is laterally disposed, and often occupies a pedunculated process; by their homogeneous texture; by their easy undulatory or serpentine outline; and, finally, by their size, which offers a breadth of 15 to 25-1000ths, and a length of 2 to 3-100ths of a line. The round nuclei of these fibre-cells, even at first sight, somewhat militate against their muscular import; but it must be recollected, that in the mammals named it has been previously stated that the muscular fibre-cells, which occur in the smallest partitions, deviate considerably from the characteristic fibres, and greatly resemble the structures now described in men. On this account, and from the further fact, that the above mentioned human fibre-cells, in moderately fresh spleens, seem to occupy the smallest partitions, just as the muscular fibres in animals; while in later periods after death, or in decomposed spleens, they can only be found isolated, with the parenchyma cells, in the red pulp of the spleen, I formerly considered it not too hazardous to regard them as muscular fibre-cells. But more recently I have made some observations which have again thrown me into complete uncertainty in respect of the import of these questionable structures. Thus I believe myself to have verified, that these fibres occur in the human subject rolled together in a kind of spherical cell (*fig.* 525. 2,) of 5 to 7-1000ths of a line in diameter; and that, on tearing up this structure they become free, and extend themselves. But, since this fact in no way harmonizes with the nature of muscular fibre-cells, and is besides altogether obscure and incomprehensible to me, I hesitate to express at once an opinion concerning the above-mentioned structures in the human spleen, but am desirous of calling the attention of inquirers to this peculiar arrangement, which, on account of its constancy and frequency, is very interesting

4. The *splenic corpuscles* or *Malpighian corpuscles of the spleen* (*vesiculæ seu glandulæ lienis, s. corpuscula Malpighii*) are whitish spherical corpuscles, which are imbedded in the red spleen substance of certain animals, and are connected with the smallest arteries. In the dead bodies of men, in the state in which they are generally subjected to examination in hospitals, these corpuscles are very seldom seen. On this account, some of the earlier observers, as Rudolphi, Heusinger, Andral, and others, and more recently Gluge * and Oesterlen †, have regarded them as not constant structures, or even as products of disease; or have considered them as J. Muller formerly did ‡, to be altogether distinct from the splenic corpuscles of the Ruminantia. But this view is erroneous, and since Giesker §, Krause ‖, and Bischoff ¶, who described the splenic corpuscles of the human subject, and showed their correspondence with those of the mammalia; and since the revocation by Müller of his earlier opinion **, all observers are tolerably agreed, that although the corpuscles in question are often deficient in the human subject, yet they are not the less to be regarded as normal structures, which are invariably present in the healthy subject.

The frequent deficiency of the splenic corpuscles is explained by many circumstances. Most of the observations of them concern human individuals, in whom a long abstinence from food has preceded death. In such cases, as Henle has well remarked ††, the apparent absence of the corpuscles is easily explicable, since their size is notoriously regulated by the quantity of ingesta. So, also, great number of the human spleens which come under our notice are diseased; either softened, distended with blood, and soaked through with extravasations, or enlarged, hardened, atrophied, or already half decomposed and putrified. Finally, the human spleen corpuscles are very delicate, and easily destroyed. As to the frequency of their occurrence in diseased subjects, we are supplied with accurate data by v. Hessling, who has given the results of 960 dissections. Of the whole number just mentioned, Malpighian corpuscles were only present in 116, or in about every eighth individual. He also adds the following numerical statement respecting the different ages of life. In the first and second year of life the corpuscles were present in every second subject; from the second to the tenth year, in every third subject; from the tenth to the fortieth year, in every sixteenth; from the fortieth year to old age, in every thirty-second. These numbers are in general correct, and are readily explicable when we recollect that diseases of the spleen are more numerous as age advances. But the results of my own observations coincide with those of Oesterlen, in representing the number of cases in which corpuscles are detected as greater than that above mentioned. This difference may be ascribed to the difficulties which often prevent the recognition of the dwindled spleen corpuscles; thus in many cases where the first view has afforded no signs of their presence, the application of soda, or the washing of the pulp, has brought them into view.

On the other hand, it is absolutely certain that, in many spleens, they disappear without leaving any traces, and cannot be made visible by any method of treatment. In the bodies of healthy individuals which are examined while fresh, they may always be detected; at least, there are very numerous observations extant in which they have been found after accidental deaths, executions, suicides, &c.; and to these cases I myself am enabled to add two. So, also, I have found them in a great majority of the bodies of children which I have examined; and here they are both very distinct and numerous, so as not to offer any visible difference, in these respects, from those of the Ruminantia.

The size of the Malpighian corpuscles experiences many variations both in men and animals, even apart from the effects of disease: they measure from one-tenth to one-third of a line; on an average, about one-sixth. Their size has hitherto been somewhat too highly estimated; and chiefly on this account, that sufficient preliminary care has not been taken to isolate them from the surrounding parts: when this is done it will be found, that they are not so large as appears from viewing them on a section of the spleen; and that, in many cases, they measure less than the given bulk. The fluctuations in their size depend not merely upon the differences of individuals, but obtain in one and the same animal: in this latter case, they appear mainly to be regulated by the condition of the chylopoietic viscera; although accurate data, as to these points in the human subject, are altogether deficient.

It is also possible, as Oesterlen has supposed, that these corpuscles experience a certain course of development; and that, in many cases, the very small corpuscles are very young and undeveloped ones: but, hitherto, I have not been able to observe facts importing the certain existence of a continual development of the Malpighian corpuscles in the adult animal; nevertheless, I cannot avoid mentioning that, like Oesterlen, I have seen in the spleens of animals little heaps (from 2 to 4-100ths line in size) of cells, which have no distinct cell walls, and which, possibly, have some relation to the formation of the splenic corpuscles. It seems quite certain that the spleen corpuscles are not developed from separate cells of the spleen pulp; although this view has lately been brought forward in a singular manner by Heinrich.*

The *Malpighian corpuscles* are imbedded in the red spleen substance, and, with the exception of one point, where they are attached to arterial twigs, they are everywhere surrounded by this substance. They are con-

Fig. 526.

nected to the small arteries and their twigs by short peduncles, like the berries of a bunch of grapes; and, in such wise, that a small arterial trunk of from 2 to 4-100ths line, with its ramifications, supports 5 to 10 corpuscles. (*Fig.* 526.) The peduncles of the corpuscles are almost always small arteries, which pass to be distributed to them; but in less frequent instances, they are constituted by short processes of the arterial sheaths, which are continuous with the membranous wall of the corpuscle. In this manner the majority of the

corpuscles are essentially devoid of a peduncle, and sit immediately on the arteries at their points of bifurcation, or at their sides. (*Figs.* 527, 258.) This relation, which also obtains

Fig. 528.

in animals, formerly appeared to J. Müller as indicating the fact that the splenic corpuscles were hollow excrescences of the vessel-walls, or were imbedded in these latter. But if by this be understood, what Müller's plates and description imply, that the sheaths of the vessels, in their whole thickness, with all their elements, are continued to form the corpuscles, then it is certainly incorrect: for in some animals I have seen that, from the rich network of elastic fibres and muscular structure of these sheaths, little or nothing passes to the corpuscles: and I have generally found the membrane of the corpuscle very delicate. It is, however, quite conformable to truth, to state that this membrane has a direct continuity with the arterial sheaths. (*Fig.* 527, 528.)

The corpuscles do not possess any connection with the trabecular network, still less that which Gerlach has lately attributed to them: viz. that they serve as points of support to the elastic fibres of the partitions; a belief which is altogether baseless.

It is difficult to say any thing definite respecting the number of the splenic corpuscles. Hessling believes that, in some cases, they constitute from one-fifth to one-sixth of the whole splenic mass; and this seems to me no overstatement, if we substitute the expression "spleen-pulp" for "spleen-mass." At least, I have found, that their quantity is very considerable; and that in some instances, when they are rather turgescent, the whole pulp appears as if besprinkled with white. They stand so thickly together, that in many places they touch each other's sides; and in others are only separated from each other by narrow interspaces, which in the least favourable circumstances are about one to two lines in size. I believe that the estimate, that one and a half to two lines of spleen-pulp contains one Malpighian corpuscle, is rather too little than too large.

As regards the lower animals, it would follow from my researches, that the Malpighian corpuscles occur in *Mammalia* in precisely the same way as in Man; at least, in more than twenty genera which I have examined, I have never found them to be absent. It has long been known that they are very distinct in pigs, sheep, oxen, goats, and so also in guinea pigs, hedgehogs, and bats, &c., in whom they are rather larger and more resisting than in Man; and although in the dog, cat, and rabbit, they are somewhat smaller and more covered by the pulp, yet they are nevertheless very distinct. As to *Birds*, Bardeleben seems to have recognised the Malpighian corpuscles in swallows, pigeons, and geese; while I have been able to verify their existence in sparrows, although they are not particularly distinct. So also Ecker briefly states, that he has seen them in birds; and Oesterlen mentions their occurrence in the fowl, pigeon, and in many of the *Raptores*. Amongst the *Reptilia*, J. Müller has detected them in the Chelonia; while I have seen them very distinctly in the anguis fragilis, in whom the corpuscles were surrounded by a beautiful network of capillaries. Amongst the *naked Amphibia*, Oesterlen states himself to have seen them here and there in toads and frogs; but in direct opposition to this, I have found no trace of them. Just as little have I been able to detect them in *Fishes*, although I have examined many of the fresh-water genera with this especial purpose. And thus the conjecture of Müller*, — that they exist in all the vertebrata, although in none so distinct or so easy of observation as in the vegetable-eating mammals — must be considered as incorrect: a cirumstance which is not without considerable interest in the determination of their import.

On inquiry into the more minute structure of the Malpighian corpuscles, it is exceedingly necessary to regard, not only their appearances in Man, but also in the lower animals. Each Malpighian corpuscle possesses a membrane and contents, and therefore is not a solid corpuscle, but rather a vesicle. The membrane which Malpighi beheld, was minutely described for the first time by Müller and Giesker. According to the first of these observers it is, as previously mentioned, a process of the common sheath of the vessels, which either immediately continues as a vesicular swelling of the same, or is previously produced into a peduncle. Giesker rejects this view, at least as regards the human subject, and describes in each corpuscle a peculiar, independent, and tolerably strong membrane, which seems to have no connection with the sheaths of the vessels, but receives an additional thin outer covering of white fibrous tissue, in which the vessels of the corpuscle ramify, and to which they frequently impart their own red colour. The majority of later observers have unconditionally adopted one or the other of these views; only a few of them, as J. Simon, Henle, Ecker, and Oesterlen, having taken the trouble of substantiating their truth by original inquiry. Henle, Oesterlen, and J. Simon, deny the existence of a special membrane. The first of these observers finds that the wall of the corpuscles is constituted solely of granules, under which appear to be comprised structures resembling the morphous part of the contents; while fine bundles of white fibrous tissue unite on their outer surface. Oesterlen and J. Simon likewise deny the peculiar membrane (limitary membrane), an absence which the latter associates with the capacity of the corpuscles to fill themselves out from the capillary vessels. So also Bardeleben describes a membrane very indistinctly.

* Physiologie, i. S. 486.

On the other hand, Ecker* has assured himself of the presence of a membrane in mammals and birds. By the application of potash, the masses of granules which seem to constitute the wall of the corpuscle were dissolved; and he then not only saw the ramifications of the arteries on the Malpighian corpuscle with great distinctness, but he also recognised that this possesses a distinct membranous wall, in which a network of exceedingly fine and well-defined stripes could be detected. Although these stripes are actual fibres, yet, according to Ecker, they everywhere cover a structureless gland-membrane, for the wall of the vesicle is never interrupted in the structureless intervals between these fibres; indeed it is possible that the latter are themselves but folds of a structureless membrane. Amongst the most recent authors, Arnold † and Huschke ‡ accept Giesker's view, and Dr. Gerlach § repeats Ecker's decision. As to myself, in the first place, I regard it as an incontrovertible fact, that the Malpighian corpuscles possess a special membrane. If one of the vesicles be isolated, and sufficiently separated from the surrounding tissues, it may be seen without any further preparation, especially with a slight pressure (*fig.* 527.); and it becomes particularly distinct if a little dilute soda or potash be applied (*fig.* 528.). These reagents dissolve all the surrounding parts of the pulp, with the exception of the vessels, and thus leave the membrane of the vesicle, although somewhat altered, yet quite entire. Concerning the nature of this membrane, I have verified the following: it is colourless, transparent, about 1 to 2-1000ths of a line in thickness, has everywhere two contours, and here and there it exhibits concentric lines. Its structure so far corresponds with that of the sheaths of the vessels with which it is continuous, that it contains at least white fibrous tissue and elastic fibres; but the unstriped muscular fibres which oc-

† Anatomie, ii. S. 123.
‡ Eingeweidelehre, S. 178.
§ Zeitschrift für Rationelle Medicin, Bd. vii. S. 77.

cur in these sheaths in many animals, are altogether absent from the membrane of the Malpighian corpuscle; and the latter must especially be noticed as being much more delicate than the sheaths of the arteries on which the corpuscles sit. The white fibrous tissue, which Ecker regarded as a continuous membrane, in consequence of having seen it when changed by the action of potash, is in precisely the same condition as in the partitions and sheaths of the vessels, and forms by far the greatest part of the coat of the corpuscles; while the elastic tissue (the stripes of a doubtful nature which Ecker saw) appears to constitute only a more or less extensive network of pale, so-called nuclear fibres (kernfasern) (*fig.* 528. *b*). So that the membrane of the Malpighian corpuscles would thus appear to be only a modified portion of the vascular sheath, — a view which most approximates to that enunciated by J. Müller. An outer coat, of which Giesker speaks, has never been plainly verified by me as a special membrane connected with the preceding; but it seems to me more probable, that the corpuscles are always immediately surrounded by the cells and vessels of the pulp. Certainly these vessels are often connected together by an indistinct fibrous or membranous substance, but this is especially present in the pulp, and is nothing else than the termination of the sheath of the vessels. The preceding remarks especially apply to the Malpighian corpuscles of the higher brute mammalia. As to those of man, although they are much more difficult to examine, yet I have satisfied myself in the most positive manner that they correspond with those of the brute mammalia in all essential points. This is easiest and best seen in the spleens of children. The structure of these is exactly that seen in animals, only the coat is more delicate, so that it is extremely difficult to isolate a single corpuscle entire, and the contents are expelled by the slightest pressure. In the wall is seen the same network of elastic fibres as in animals, and this renders it possible even to recognise those which are burst. Extremely fine capillaries of 3-1000ths of a line in diameter may frequently be seen around the corpuscles; but the latter are just as little enveloped in a second membrane as in animals.

The Malpighian corpuscles do not possess in their interior an epithelium and separated contents like the glands, but they are densely filled with a semifluid, greyish white, cohesive mass (*fig.* 527. *b*). This contains, together with a small quantity of a clear fluid, a large quantity of morphous particles, which have been very differently described by different observers. According to J. Müller they very much resemble the corpuscles of the spleen-pulp, and have a general likeness to the blood discs, but are irregularly spherical. Bischoff regards them as altogether corresponding with those of the chyle, both in appearance, size, and behaviour with water and acetic acid. According to Henle, they resemble those of the spleen-pulp and those of the thymus and thyroid body; and he so describes them, that it would appear he recognised nuclei and a small proportion of cells. Oesterlen describes them as nuclei resembling the elements of the pulp. Hessling, Huschke, and Nasse* agree with Bischoff respecting the similarity of the elements in question to the lymph and chyle corpuscles. The latter of these authorities finds those of the rabbit to be 2—3-1000ths of a line in diameter, while Hessling certifies to their size in men as from 2—5½-1000ths, and describes their surfaces as possessing a mulberry-like appearance, and their contents as partly minute granules, partly separate nuclei. J. Simon found that the corpuscles in question never attained a development into cells. Remak† describes them as consisting — partly of large transparent cells, with an interior containing a single lateral, or double and clear nucleus — partly of small, dark-bordered vesicles, closely surrounded by a delicate pale membrane, and occupied by a dark central nucleus. The first, according to him, resemble the larger, the last the smaller lymph corpuscles. Finally, Gerlach finds in the Malpighian corpuscles the nuclei of cells, and, in equal quantity, cells of different sizes, with one, two, or three nuclei, as well as blood corpuscles, with all those forms of granule-cells which I shall hereafter describe as developed in the spleen-pulp from the effused blood.

These are the most important accounts given by others. As the result of my own researches, I must, firstly, corroborate J. Müller, who explains the elements of the contents of the Malpighian corpuscles and spleen-pulp as similar structures. Also, I can add with Bischoff, that they often resemble the chyle corpuscles; yet I am not disposed to lay any weight upon this correspondence. Furthermore, I consider it fully made out that Gerlach's view, according to which blood corpuscles, and cells which include blood corpuscles, are a constant constituent of the Malpighian corpuscles, is altogether erroneous. They are not even frequent occurrences, for in many animals I have not found them at all; and when they occurred — as, for instance, in oxen — they were mostly found in scattered vesicles, and, further, were in such small quantity, that they had no influence on their colour. And very often blood corpuscles and their metamorphoses appeared to occupy the vesicles, where a more careful examination showed that they were only in contact with their outer surface. The degree of accuracy to which Gerlach's assertion may lay claim is best shown by the fact, that he altogether denies the existence of these granule-cells (which are produced from the effused blood) in the spleen-pulp; while it is here, as well in these as in animals which possess no proper spleen vesicles, that they occur in

* Handworterbuch der Physiologie, von R. Wagner, ii. S. 387.

† Diagnostische und Pathogenetische Untersuchungen: Berlin, 1845.

the greatest quantity, and are most easily seen.

The constant and essential elements of the splenic vesicles are cells, with a single nucleus of a spherical shape, and from 3 to 5-1000ths of a line in diameter: besides these, free nuclei, and larger cells of 6-1000-ths of a line in diameter, and with one or two nuclei, also occur (*fig.* 529.). The cells are in general pale and faintly granular; their nuclei are from 16 to 25-10000ths of a line in size, spherical, apparently homogeneous, and with a rather dark margin; or frequently vesicular, with a more or less distinct nucleolus and other granules. It is not infrequent to see

Fig. 529.

a, smaller cells; *b*, larger cells; *c*, free nuclei.

single cells provided with dark fatty granules, and in particular instances blood discs are present, either changed or unchanged, free or included in cells. The free nuclei are of the same size as those contained in cells, and are also, in other respects, quite similar to them. In the ordinary method of examining the Malpighian corpuscles, the quantity of the nuclei seems larger than it really is, since many of the cells burst, and allow their nucleus to escape. Yet it is very remarkable that their number is very variable in the most cautious examination, a fact which appears to me partly to account for the very different statements of different observers. In many cases it has happened to me to find only a few free nuclei, often none at all, while in other instances they constitute a half or more of the elements of the corpuscles. This fact, taken together with the often very different size of the cells present, seems to prove that a continuous process of cell-growth exists in the Malpighian corpuscles; in such wise, that new nuclei and cells continually arise, and old cells perish. But hereof more will be said in speaking of the pulp, in which the same process obtains.

If, after these remarks, we take a glance at the import of the Malpighian corpuscles, we shall be compelled especially to ask ourselves, first, whether they are the beginnings of the lymphatics, or in any other way connected with them? and, secondly, whether they have the import of glandular vesicles? A connection of the Malpighian corpuscles with the lymphatics was a belief of many anatomists in earlier times, and in our own days has been recently upheld by Giesker, Huschke, Gerlach, and Poelmann. The acceptors of such a theory rest mainly on conjecture, but partially also on facts. Amongst the latter, there may be mentioned — 1. The correspondence of the cells in the Malpighian corpuscles with the lymph corpuscles. But we must remember that cells which correspond with the lymph corpuscles occur in many other situations where no such connection with the lymphatics can be imagined, as in the spleen-pulp itself, in the pancreas, in the salivary glands, the glands of mucous membrane, the thymus, thyroid, &c. 2. Huschke adduces the similarity of the spleen vesicles with the whitish granules of the lymphatic glands, which are dilatations of the lymphatic vessels themselves. Against this it need only be objected, that this latter is a pure fiction of Huschke's, and that even were it as he states, no conclusion concerning the nature of the Malpighian corpuscles could fairly be deduced from it. I have yet further to mention, that, according to an oral communication of Ecker which was made to me many years ago, and recently repeated, concerning the splenic vesicles of the mammalia, processes and pedicles exist which are neither blood-vessels nor partitions, and, therefore, may be lymphatics, — a view with which Poelmann's and Gerlach's recent statements are somewhat in unison. The former of these two* says that he followed the thoracic duct even to the Malpighian corpuscles, with which it became connected; but he does not specify more exactly the nature of this connection. The latter says that it has often seemed to him as if the neighbouring Malpighian corpuscles communicate with each other through special tubes; that he has been led to this belief by the circumstance that when the vesicles are compressed, their contents are expelled in definite directions, which a closer examination shows to be canals, the coats of which tolerably resemble in texture those of the Malpighian corpuscle; and that it is thence clear that the corpuscles communicate with a system of tubes which can scarcely be imagined to be any thing else than the lymphatics. And thus, if the Malpighian corpuscles are dilatations of the lymphatics, they may possibly be commenced as simple varicose swellings, or, what is more probable, as lateral productions of these vessels. I acknowledge that I am unable to verify this fact last adduced, or to subscribe to this connection of the Malpighian corpuscles with the lymphatics. In my researches I have given an attention to this point conformable to its great importance; and although I have not seen the commencement of the lymphatics in the spleen, yet I have so far come to a positive conclusion, that I am convinced of the complete closure of the Malpighian corpuscles. What Gerlach states of the tubes into which the contents of the corpuscles are forced, is altogether erroneous; such tubes nowhere exist. Gerlach appears to have been misled to this opinion by the fact, that when a corpuscle is burst by pressure, the contents rush out at several points,

* Annales et Bulletin de la Société de Médicine de Gand, 1846, p. 267.

and are then effused in the shape of long and small streaks in the surrounding tissues. If the commencements of such a streak were not observed, it might easily be regarded, from its always taking a radiating course from the Malpighian corpuscle to which it is united, as a canal communicating with the same, especially when a longer pressure applied to the corpuscles has elongated these stripes by continually forcing out the contents. The processes which Ecker has described on the Malpighian corpuscles, and which are not bloodvessels, probably belong to the same category as the artificial products mentioned above; or, if this is not the case, it is possible that they are small trunks of nerves, which are frequently present in the neighbourhood of Malpighian corpuscles, and which, from reasons that will be hereafter mentioned, are exceedingly difficult to recognise as being what they really are. I therefore maintain, quite plainly and definitely, *that the Malpighian corpuscles are closed capsules, and stand in no connection at all with the lymphatics.*

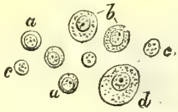
If this be so — and the structure of the Malpighian corpuscles, which altogether differs from that of vessels, corroborates the fact — it is next demanded may not the Malpighian corpuscles be glands? If by "glands" be meant the word in its ordinary sense, I answer with a decided "*no;*" for these altogether differ from the known simple shut glandular sacs of the ovary, thyroid, thymus, and supra-renal capsules, and possess neither a structureless membrana propria (limitary membrane, or basement membrane) nor an epithelium. On the contrary, in my opinion, they correspond with the spaces filled with cells in the lymphatic glands, and with the sacs of the glandulæ solitariæ and agminatæ of the intestine. Here and there hollow spaces exist, which possess a covering of white fibrous tissue, are completely inclosed, and contain in their interior no trace of epithelium, but only a coherent mass of nuclei and cells, together with some fluid; we might call these "*vesicular glands*," recollecting at the same time that they possess the function of the real shut glandular vesicles, although their anatomy essentially differs. Although the discussion of the former question does not belong to this part, yet I will add, that, in reality, there is much to indicate that the structures in question constitute a kind of shut glandular vesicle; and that, consequently, there is nothing to prevent their being regarded as glandular vesicles.

5. *The red spleen substance, the spleen-pulp, the parenchyma of the spleen* (*substantia rubra, pulposa, parenchyma lienis*), is a soft reddish mass, which fills up all the interstices between the larger partitions and the stronger vessels, and on section of the organ is easily scraped off or squeezed out. It consists essentially of three constituents; which are, fine bloodvessels, parenchyma cells of the spleen, and small partitions or fibres. To these constituents is so frequently added, both in man and animals, extravasated or coagulated blood in various metamorphoses, that one is almost forced to designate it a normal constituent. According to the predominance or diminution of the latter ingredient, or according to the greater or lesser distention of the bloodvessels themselves, the spleen-pulp appears sometimes altogether of the colour of the blood, at others of a clearish red, with a greater or lesser tendency towards whiteness.

The following remarks apply to the microscopic appearances of the constituents of the pulp, the vessels only excepted, which will be described hereafter. The fibres of the pulp are of two kinds. The one kind, which may be named "small or microscopic partitions" ("*microscopische balkchen*"), are quite analogous to those larger partitions ("*balken*") which are visible to the naked eye; they are also of the same structure, except that in the lower animals they often contain more muscular fibres than the latter. Their diameter is variable, from 5 to 10-1000ths of a line; their frequency and quantity also vary in different situations, and amongst different creatures. In the human subject I find them to be fewer and broader than amongst other mammalia, and exactly like the larger partitions in structure; while in the ox, sheep, &c., they occur frequently, are more delicate, and are remarkable by their purely muscular structure. The other fibres of the pulp are evidently processes from the sheaths of the larger vessels; they greatly predominate in quantity, and appear chiefly in the form of delicate membranes of an indistinctly fibrous structure, and without any mixture of elastic fibres, which seem to connect the capillaries to each other. Whether they take the form of small partitions — in which case they could not be distinguished from the small *trabeculæ* — is at present undecided. In animals, these membranes are also present on the veins; but of this more will be said hereafter, in speaking of the vessels.

The *cells of the spleen-pulp*, which I shall call "parenchyma-cells of the spleen," have been described by J. Müller as similar to those of the Malpighian corpuscles; and, as was previously stated, this view has been followed by the majority of writers; as by Henle, Bischoff, Huschke, Remak, and others. Only Von Hessling and Gerlach are of another opinion. According to the former, the globules of the spleen-tissue are distinguished by their dark colour, and by their being mingled with spindle-shaped cells. Gerlach finds that cells with nuclei are rare in the spleen-pulp; while, on the contrary, he considers them to be frequent in the Malpighian corpuscles. As to myself, I have already expressed my concurrence with the view taken by Müller, and may therefore forbear to enter further upon this point; nevertheless, it is necessary to remark that the parenchyma-cells exhibit some additional peculiarities, which ought not to be passed over without notice. A considerable portion of these cells completely correspond with the cells of the spleen vesicles; the characteristic appearances of which are their

Fig. 530.



Parenchyma-cells from the spleen of the Ox, magnified 350 diameters.

a, Smaller cells; *b*, cells of medium size; *c*, free nuclei; *d*, largest cells.

roundness, their size — from 3 to 5-1000ths of a line — their paleness, and their dark nucleus (*fig.* 530. *b*). On the other hand, smaller and larger corpuscles also occur in the spleen-pulp, which are never met with in the Malpighian corpuscles. The former are small round corpuscles, somewhat larger than blood globules. They are seen in one of two states: either they exhibit a membrane and nucleus inseparable from each other, and thus, apart from their colour and somewhat lighter outline, resemble blood globules; or they are free nuclei, in which no nucleoli are visible. But only a few of these are free nuclei, for by the application of saliva or a little water a membrane starts into view, either completely enclosing them, or limited to one side (*fig.* 530. *a*). The nuclei, which thus appear as something separate from the membrane, have always the dark appearance of those cells the two parts of which are inseparable from each other; so that the appearance of these latter would seem chiefly dependent on the nucleus. With these small and quasi-developing cells, one also meets with free nuclei; and careful manipulation of the preparation shows these to be in general more numerous than in the Malpighian corpuscles (*fig.* 530. *c*). The larger named corpuscles are partly pale cells of 7-1000ths of a line in size, with one or two nuclei; or granule-cells of 4 to 6-1000ths of a line, and which may be described as "the colourless granule-cells" (*fig.* 530. *d*): both of these are more frequent than in the Malpighian corpuscles. The spindle-shaped or fusiform cells which Hessling mentions do not belong to the normal constituents of the spleen-pulp, and are nothing else than epithelium cells of the splenic arteries (*fig.* 534. *b*), which in macerated specimens of the human spleen, and in preparations where the vessels have been cut through, easily get into the pulp, and give rise to the delusive appearances of the so-called fusiform cells. The comparative examination of this part of the spleens of many animals confirms what has been already stated of the elements of the Malpighian corpuscles; namely, the elements of the pulp vary greatly, since sometimes the nuclei, sometimes the smaller cells, sometimes the greater cells, predominate. And in this, as in the former case, I conclude therefrom that a continuous process of cell growth obtains in the spleen, by which new cells are formed around nuclei, and old ones disappear.

The quantity of parenchyma-cells of different kind and shape, and of free nuclei which must be reckoned with these, is a very considerable one; so much so, as to constitute nearly one half of the whole red spleen substance. These do not lie collected in large heaps, but constitute small irregular groups of different size, which occupy the interspaces formed by the partitions of all sizes, the vessels, and the Malpighian corpuscles. The best method of representing this disposition is to regard each part of the pulp, which is included in a large mesh by trabeculæ visible to the naked eye, as constituting in a small form what the spleen itself is in a larger. The microscopic partitions and fibres and the finest vessels thus exhibit the same relations as the larger partitions and vessels; while the small nests of parenchyma-cells answer to the large homogeneous masses of red pulp which are visible to the naked eye. There are nowhere any special coats which include these cells, but they may be seen everywhere placed immediately on the sheaths of the vessels, the partitions, and the membranes of the Malpighian corpuscles. In the above delineation of the parenchyma-cells, those of man and of the higher mammalia have especially served as the model: but in general a complete similarity obtains in other animals; and it is only here and there that any specialities show themselves. In many animals — thus, for instance, in amphibia — the spleen has often, though not always, very beautiful parenchyma-cells with large nuclei: in birds, and in the scaly Reptilia, granulated and somewhat dark cells are for the most part more frequent. In the hedgehog, rabbit, and guinea-pig, some cells, which are altogether peculiar, occur in company with the ordinary ones. In both the former of these I saw, here and there, large round cells from 10 to 16-1000ths of a line, with three, four, to ten or more nuclei, which often lay so closely together in the middle of the cell that they appeared to make up a mulberry-like mass, like certain large cells which one finds in the marrow of young bones. These cells were by no means uncommon, but gradually diminished in size towards that of the parenchyma-cells. In the guinea-pig occur round cells, in large quantity, of 48 to 60-10000ths of a line, which contain one or seldom two round granules of a dark contour; and their nucleus, not always very distinctly visible, is very plainly seen on the application of acetic acid; while, at the same time, the dark granules often disappear.

The *blood effused in the spleen-pulp*, as well as the *metamorphoses of the blood globules* in the same, demand the greatest consideration both in respect of anatomy and physiology. I believe myself to have been the first who* directed attention to this circumstance, and cor-

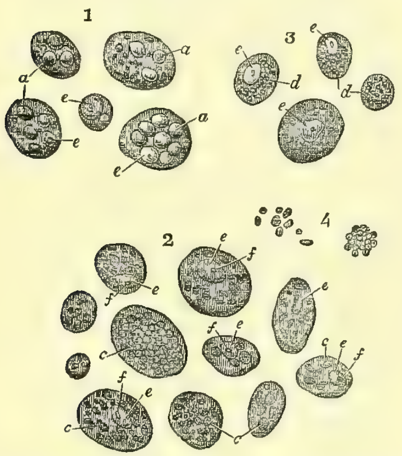
* Loc. cit.

rectly recognised it; although Oesterlen, Remak, and Handfield Jones had already detected isolated facts having a reference to it. Oesterlen * was the first who found in the spleen of frogs and toads, and with less distinctness in that of the mammalia, yellow, rose-red, and black minute corpuscles, but he was not in a condition to explain them. Remak followed next without greater success; he found in the spleen-pulp of the calf delicate transparent vesicles, with 1 to 3 round, reddish-yellow homogeneous bodies, the colour of which approximated to that of the blood corpuscles, but which were not so easily swollen out by water. Finally, Handfield Jones † discovered peculiar yellow corpuscles in the spleen of different vertebrata.

All these facts are placed in their true light by my discovery that blood corpuscles are almost constantly undergoing dissolution in the spleen and disappearing. This will be shown as follows: —

The red pulp of the spleen in man and animals exhibits at different times a different

Fig. 531.



Cells containing blood corpuscles from the spleen of the Rabbit, magnified 350 *diameters.*

1, cells with one, three, four, and seven unchanged blood corpuscles; 2, cells with blood corpuscles undergoing dissolution, and coloured in different shades of brown or yellow (coloured granule cells); 3, cells with destroyed and decolorized blood globules, larger or smaller, and with or without granules; 4, blood globules altered in colour, diminished or destroyed, either single or aggregated, in small clumps.

In 1, 2 and 3 the following letters signify alike: — *a*, more or less unchanged blood globules; *c*, colored granules begun by a diminution or destruction and alteration of colour in blood corpuscles; *d*, colourless granules produced by the discoloration of *c*; *e*, nuclei of the cells containing blood corpuscles and their metamorphoses; *f*, nucleoli of these nuclei.

colouring, or rather a different condition of the blood corpuscles contained in it, and these, without any participation of the other elements, affect its colour by the different nature of their appearances. Thus, in a particular animal or in the human subject, this substance sometimes possesses a paler or more greyish red, sometimes a brown, or even black-red colour: in the latter case a quantity of altered blood globules are present, the appearances of which will hereafter be described; while in the former case, it may easily be proved by the microscope that the red colour depends on unaltered blood globules, which are easily separated from the pulp by pressure, and on the application of water give off all their colour in a short space of time. In other animals, the spleen has always about the dark colour mentioned: nevertheless, even in these cases, sometimes only unchanged blood globules are seen; sometimes many of these are undergoing the most manifold changes.

Now these changes (*figs.* 531, 532.) are very extraordinary and peculiar, and in all animals depend essentially upon these facts. The blood globules first become at once smaller and darker, while the elliptical corpuscles of the lower vertebrata also become rounder: then, in connection with some blood plasma, they become aggregated into small round heaps; which heaps, by the appearance of an interior nucleus and of an outer membrane, experience a transition into spherical cells containing blood corpuscles. These are from 5 to 15-1000ths of a line in size, and contain from 1 to 20 blood corpuscles (*figs.* 531. 1. 532. 1.) During this time the blood corpuscles are continually diminishing in size, and, assuming a golden yellow, brownish-red, or dark colour, they undergo, either immediately or after a previous dissolution, a complete transition into pigment granules. So that these cells themselves are changed into pigmentary granule-cells; and, finally, by a gradual loss of colour of their granules, they form themselves into completely colourless cells (*figs.* 531. 3. 532. 4.).

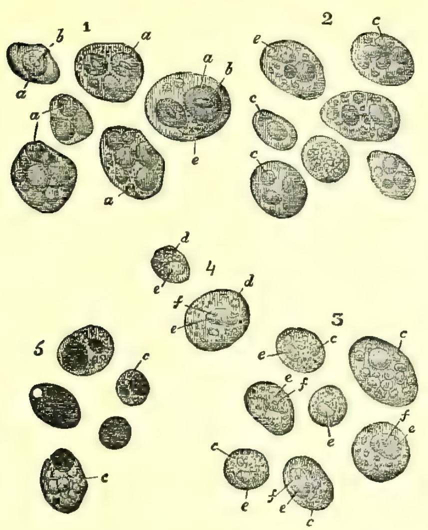
In respect of the more special circumstances of this process, it is first necessary to consider the commencement of the cells described, and their changes, somewhat more in detail. As regards the first of these, it is certain that the cells containing the blood corpuscles do not commence directly around a nucleus, but by the circumposition of a membrane around a heap of coagulated blood: in the same way, to wit, that the so-called inflammatory globules of Gluge in certain cases change themselves to cells; or that by which the smaller globules of fission of the yolk form themselves into vesicles. On the other hand, it remains doubtful whether the nuclei which are seen in these cells are there before the formation of the membrane, or whether they only begin as supplementary to it. If the former be the case, one might add that, in the extravasated or clotted blood of the spleen, nuclei arise in consequence of the commencing organization, each of which then, like the nuclei in the fission of the yolk,

* Loc. cit. p. 52.

† London Medical Gazette, Jan. 1847, pp. 140-142.

surrounds itself with a part of the blood (plasma and globules), and, finally, conditionates the development of a membrane on the surface of the sphere thus commenced. Or one might regard the formation of spheres consisting of some blood plasma and blood globules as the primary phenomenon; and that then a nucleus begins in each sphere; and that, finally, a membrane is thrown around these. In corroboration of this opinion, Hasse and myself* have observed in the pigeon the occurrence of inflammatory globules, which are without nuclei or membranes, but contain blood globules; and to this may be added, that in the splenic extravasations blood corpuscles are often grouped together in heaps without being contained in cells. Be this as it may, in any case thus much is certain, that as soon as the cells with their included blood globules are visible, the nuclei are never absent; and this fact, taken in conjunction with what is already known of the import of nuclei in the process of cell development, speaks strongly for their formation preceding that of the membrane of the said cells.

Fig. 532.



Cells containing blood corpuscles, from the spleen of the Frog (Rana temporaria and esculenta), magnified 350 diameters.

1, cells with one or more blood globules of an intense yellow colour, diminished in size, yet mostly not yet destroyed; 2, cells with blood globules coloured brown, orange, or black, still more diminished and dissolved (coloured granule cells); 3, cells with blood globules much diminished or quite dissolved, and undergoing discolorization (pale-coloured granule-cells); 4, cells with completely dissolved and discolorized blood globules (colourless granule-cells); 5, coloured granule-cells (like those in 3) in different stages of their transition into black pigment-cells.

In 1—5 the letters import, as in *fig.* 351. *b*, the nuclei of the blood globules.

These cells containing blood corpuscles behave themselves so far alike in all creatures, that their blood corpuscles by degrees disappear and fall to the ground; and, ultimately, they all seem to be converted into colourless cells, although the methods by which this change occurs are different in different animals; whence it will be well to go through them one by one.

a. In *mammals* the cells with unchanged blood corpuscles are not very easily seen, on account of the small size of the latter, and the facility with which they lose their colour; yet one can easily get a sight of them, provided the examination be made at the right time, and the application of water forborne. I have seen them plainly in man, the rabbit (*fig.* 531. 1.), guinea-pig, sheep, calf, and dog; and have found that in these creatures the number of the included blood globules is from 1 to 12, on an average from 2 to 6, and the size of the cells from 5 to 16-1000ths of a line; while their vesicular nuclei have a length of 36-10000ths, and a breadth of 28-10000ths of a line. By the shrinking up and falling to pieces of the blood globules, which immediately renders them darker in colour, coloured granule-cells begin from these cells. They are of a golden yellow, or rusty or brownish yellow, or even blackish colour (*fig.* 531. 2.), and gradually experience a transition into cells, with slightly coloured, more numerous, and smaller granules; and, finally, they take the form of altogether colourless cells, part of which are even poor in granules (*fig.* 531. 3.). In man, the rabbit, and the guinea-pig were found, besides the cells just described, free granules and heaps of granules, of a golden yellow, brown, or blackish colour; together with altered blood globules, concerning which it seemed to me very probable that they were originally free, and were never included in cells. In other vertebrata, as in the hedge-hog, the cat, and the bat (*Vespertilio myotis* and *pipistrellus*), the cells with the unchanged blood globules were not observed, although all other stages, from the golden yellow to the altogether colourless granule-cells, were seen. Finally, in others, as in the horse and ass, were seen uncommonly numerous, diminished, and highly coloured blood-globules, both isolated and aggregated; and the metamorphoses of these into golden, brown, and blackish-yellow heaps of granules, although no definite indication of cell structure could be detected around these heaps.

b. Amongst *birds*, I have found the round cells in Falco albicillus, Cuculus canorus, Turdus varius, Perdix saxatilis, and Sylvia hortensis. They were in larger or smaller quantity, from 4 to 10-1000ths of a line in size, with dark golden yellow granules which were evidently nothing but metamorphosed blood globules. This was very distinctly shown in Turdus musica, since here the cells occurred with unchanged blood globules. Everywhere these cells experienced a transition, partly into brown and black granule-cells, partly into colorless granulated cells.

c. Amongst the *Reptilia*. In the *scaly*

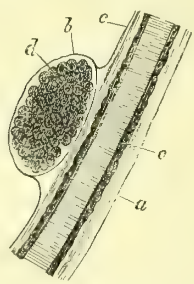
* Zeitschrift für Ration. Medicin, Band. iv. S. 1.

Reptilia, amongst which I have only examined Anguis fragilis and Coluber austriacus, I have seen no cells with unchanged blood globules; but in the Anguis I found pale yellow, brown, and black granule-cells, which were, as in birds, of from 6 to 10-1000ths of a line in diameter. Transitions of these into faintly yellowish and colourless granule-cells were also present in considerable number, being almost as frequent as the ordinary parenchyma cells in the spleen-pulp. The Coluber austriacus certainly exhibited an effusion of blood in the parenchyma of the spleen, but no changes of the blood corpuscles. The *naked* amphibia offered a striking contrast. Amongst them I examined Rana temporaria and esculenta, Bombinator igneus, Hyla arborea, Bufo cinereus, Alytes obstetricans, Salamandra maculata and atra, Triton igneus, tæniatus, and cristatus. The cells with blood globules were better seen in these than in any other animals. This was especially the case in Triton, Bombinator, and Rana, in which 5, 10, 20, and more blood globules, with distinct nuclei, were frequently seen occupying a plainly nucleated cell of 6 to 12-1000ths of a line in diameter. The size of the blood globules in these cases allowed their metamorphoses to be followed through all stages, as is represented in *fig.* 532. At first they were round, of an intense yellow, and less easily altered by water; then they contracted themselves yet more together, assumed a golden yellow or brown yellow colour, and were no longer assailed by water; finally, they became colourless, or experienced a transition into black granules, while they generally also fell asunder into smaller granules. In this manner golden and brownish yellow granule-cells (*fig.* 532. 1.) arise from the cells with unchanged blood globules (*fig.* 532. 2, 3, 5.), and finally they experience a transition into colourless granule-cells (*fig.* 532. 4.), or exist for a longer time as black pigment cells.

d. In *fishes* I have recognised the same conditions as in the naked amphibia, only they were not so brilliant. The cells with blood globules were very distinctly seen in Salmo fario, Cyprinus carpio and brama, Tinca chrysitis, Esox lucius, Perca fluviatilis, Coregonus muræna, and Gadus lota. In Anguilla fluviatilis, Aspius alburnus, Chondrostoma nasus, leucocephalus, &c., they were less plainly seen; nevertheless, cells with shrunken blood corpuscles, or aggregates of such, occurred also in these. In all fishes these structures become converted partly into colourless granule-cells, partly into black pigment-cells and pigment masses, which finally often lose their colour.

The *place* where the changes of the blood corpuscles above mentioned occur can be demonstrated in some amphibia to be the bloodvessels. Thus, in Triton igneus, the spleen is at its margins tolerably transparent, and here one frequently comes upon the cells which contain blood corpuscles, occupying the capillaries in a row one after another; and here we are also able to drive them into the larger venous channels by pressure, so that one of these is often filled by a considerable streak, consisting entirely of these altogether characteristic elements. Whether this occurrence is a rule in the Triton, and whether it obtains in other amphibia, I am unable to certify. Yet I may communicate that, in the Triton, frog, toad, and Salamandra atra, I have found these cells containing blood corpuscles even in the trunks of the splenic vein and vena portæ; while in Bufo cinereus, Triton igneus, and Salamandra, I have found them in the hepatic branches of the vena portæ, even to its capillaries; and in the latter animal, even in the inferior cava and the heart. In any case, these facts may be considered as conclusive of the not unfrequent occurrence and formation of the cells in question within the bloodvessels of the spleen; although it can scarcely be added that they are not probably also formed in the extravasated blood. In certain genera of fishes, as in Tinca, Esox, Perca, the cells which contain blood corpuscles, and their metamorphoses, are seen included in round delicate-walled vesicles of from 1-40th to 1-16th of a line in diameter (*fig.* 533.), which for the most part

Fig. 533.



Artery (a), with a cyst (b) in its tunica adventitia (c), which contains cells (d) enclosing blood corpuscles. From the spleen of the Tinca chrysitis.

sit on the ramifications of the splenic arteries, either laterally on the vessels, or on the points where they divide; and which are connected with the sheath or exterior membrane of the same; or, in other words, are nothing else than *pouchings* of the same. How these vesicles are developed I have not determined, yet I can scarcely doubt that they have the import of false aneurisms, and owe their origin to a tearing of the inner and middle tunics, and to a protrusion of the tunica adventitia, together with the sheath of the vessels (if the latter texture can be supposed to exist here). The similarity of these vesicles with the Malpighian corpuscles of the mammals seems to be especially worthy of mention. After the description already given of the relation of the Malpighian corpuscles to the arteries, it is unnecessary to explain in detail, that the correspondence of both in respect of their site is very great. But, in respect of their contents a similar resemblance is sometimes exhibited, when, as in the cysts of fishes, the cells with blood corpuscles have all undergone a transition into colourless cells, or the Malpighian corpuscles contain effused blood. By pondering upon these circumstances, one might almost come to the idea of regarding the cysts of fishes as Malpighian corpuscles, or the Malpighian corpuscles of mammals as false aneurisms of the splenic arteries ; but in my opinion either of these views would be altogether erroneous. For although blood is often present in the Malpighian corpuscles, yet this appearance is *much too seldom* to allow of our explaining their contents as arising out of altered blood. And as regards the cysts of fishes, they are altogether absent from many fishes, and, where they are present, often undergo a cretification, or are changed into concretions ; while they occur in other organs, as for instance in the kidneys : facts which have little conformity with the constant occurrence of the Malpighian corpuscles. In others of the fishes previously mentioned, no vesicles can be recognised in the spleen; on the contrary, in many genera, the blood corpuscles obtained in different conditions of their metamorphosis are seated together in roundish heaps of a more or less definite outline, and of a size which equals that of the vesicles : these are evidently nothing else than extravasations of blood. The numerous circumscribed red or brown points which occur in the spleen pulp of all fishes, are nothing but the self-decomposing blood globules ; and they are, as above mentioned, either free or arranged in masses which are included in vesicles. In the scaly reptilia, birds, and mammals, it is very difficult to state with certainty in what part of the spleen the formation of the cells which contain the blood corpuscles and their metamorphosis occurs. At first I thought of the hollow interspaces with which the vein of the spleen begins; only these spaces, as will be shown hereafter, do not in the least obtain in the human subject in the form which has been hitherto attributed to them. Or the branches of the veins, which are always large, might easily be regarded as the locality, provided that the occurrences above mentioned be not regarded as extravasations. With regard to this question direct observation teaches us as follows. In the capillaries and arteries of the spleen in mammalia no changes of the blood corpuscles exist; so that the only question is, whether the blood corpuscles, which constantly occur in the spleen-pulp, and here undergo their metamorphoses, are situated in the commencements of the veins; or whether they occupy spaces newly formed by the extrusion of thē blood. Much may be adduced in support of the first of these views. Thus, it is scarcely possible to suppose that extravasations of blood in such extraordinary quantity constantly occur in the spleen; then it may also be mentioned that pigmentary granule-cells, such as are developed in the spleen from the blood, may also be found in blood-vessels exterior to the spleen, which seems to speak for their being situated within the vessels in the case of the spleen itself. I have myself formerly found scattered pigment-cells in human blood * which I can now only regard as granule-cells from the spleen. Ecker has also seen † in the splenic veins of the calf, cells containing blood corpuscles like those in the spleen. And, lastly, Meckel ‡ has also found black pigment-cells in the blood of a woman whose spleen abounded in them. Finally, we may recollect, that in the amphibia the cells in question are certainly situated in the vessels. But, on the other side, it must not be forgotten that in the spleen of fishes metamorphoses of the extravasated blood take place, and that also portions of the extravasations enter the vessels, and that it is possible the pigment-cells in the blood may thus originate ; finally, that the masses of blood in the spleen-pulp are scarcely defined with the sharpness which they would possess even in veins with very delicate coats. In this state of things it is much better to abstain from giving a definite decision ; or if one be absolutely required, to attribute the metamorphoses of the blood in the spleen of mammals to both the localities mentioned.

The changes of the blood globules in the spleen are not exactly similar in all circumstances, either as regards the quantity of the cells thus changed, or the degree of metamorphosis which they undergo. In *fishes*, all the blood globules, without exception, may be recognised as decomposing; yet the quantity of these varies, *i. e.* the number and size of the vesicles and masses previously described varies in a considerable degree in different individuals and species, although no very definite laws have as yet been found out. *Reptilia* exhibited the following peculiarity. In newly-caught individuals, the cells containing blood corpuscles were very numerous and distinct ; but in those which had fasted one, two, or three days, they occurred in exceedingly small quantity ; while, finally, by a longer duration of the fasting (a week or more), they exhibited themselves in very great number, and of extraordinary distinctness ; while at the same time the spleen became large, dark red, and very rich in the normal blood corpuscles. When newts which had fasted a week were fed, the cells previously existing, and the unchanged blood corpuscles, vanished, since they were changed into colored granule-cells, and only on the sixth day after the feeding did such cells reappear ; but in three days afterwards almost all of these had again experienced a metamorphosis into granule-cells. In *mammalia* I have, in a series of cases, seen the decompositions of the blood corpuscles in as little as five, six, and more hours after eating, while immediately after the reception of food, or after a day's fasting, I have failed to observe it. At my advice, Landis § instituted experi-

§ Beiträge zur Lehre über die Verrichtungen der Milz: Zurich, 1847.

ments concerning this on thirty rabbits, and obtained the following results. Of fifteen animals which were examined, two, five, and eight hours after eating, cells with unchanged blood globules were found in eleven ; in five they were in masses ; in six separate ; in four cases they did not occur at all. Fifteen other animals, which were killed twelve, twenty-four, and forty-eight hours after eating, showed in eleven cases no trace of the cells mentioned; in two cases many were present, in two cases a few only. And, *vice versâ*, golden yellow granule-cells (*metamorphoses* of the cells with unchanged blood globules) occurred fourteen times in the latter animals; ten times in great quantity, once in considerable numbers, and three times very sparingly, while in one instance only were they altogether wanting. In the fifteen animals first mentioned these were twice absent, five times sparingly present, twice in considerable numbers, and six times in large quantity. The conclusion to be deduced from these facts is, that cells with unchanged blood globules only show themselves a short time after eating, and that the granule-cells which proceed from these are almost always present, although in greater number in animals which have fasted a considerable time. If any animal were examined at the proper time, one would be astonished at the uncommon quantity of decomposing blood globules; for in such a case the whole red part of the pulp consists (so to speak) of nothing but golden yellow or blackish corpuscles, which are the different metamorphoses of blood corpuscles already mentioned.

Of the *ultimate destiny* of the blood corpuscles so metamorphosed, thus much is certain,—that they are decomposed and dissolved ; but, on the other hand, it is difficult to make out what is the destiny of the cells which usually enclose them We have already seen above that these cells occur in the splenic vein, the vena portæ, and the inferior cava, and it is thence questionable whether all these cells may not possibly pass into the blood. It is difficult to give an answer to this. Thus much I consider to be made out : —that cells with unchanged blood globules, and yellow, brown, or blackish-yellow granule-cells, only exceptionally and seldom pass into the blood of the splenic vein, or beyond ; since, in the first place, these cells are, upon the whole, rarely found in the blood ; while, secondly, their occurrence in the spleen is demonstrably very frequent. On the other hand, as to the colourless granule-cells which finally arise from the cells containing blood corpuscles, it is not made out whether they remain in the spleen or enter the blood. Supposing the first of these to be the case, they may either abide a considerable time in the pulp, and then in a certain manner serve as parenchyma-cells, with which they have a great similarity, or they may experience a dissolution, and altogether disappear. In the second case, one may imagine that they are converted into lymph corpuscles, with which they have, to some extent, a great similarity, or that they undergo a solution in the blood of the portal vein and the rest of the circulation. I own that I cannot hazard a decision. It is certain that colourless granule-cells occur in the blood as well as in the spleen ; but it is also certain that they are much more frequent in the spleen, and that, as regards the blood of extravasation which undergoes metamorphosis, it may be definitely stated, that its products for the most part remain in the same place.

So much for my experience of the decomposition of blood corpuscles in the spleen. Simultaneously with myself, Professor Ecker, of Basle, made similar observations, which likewise referred to a destruction of blood corpuscles, and which, soon after, lent an additional light to mine.* In contradiction to this, however, Gerlach has lately uttered the opinion that my observations allude to the formation of colored corpuscles within colorless ones; so that he explains the forms of cells which are found in the spleen in precisely the reverse way, and supposes that the cells with golden yellow granules are the younger, and those with unchanged blood corpuscles the elder ; that is, that they are those in which the blood corpuscles have completely developed themselves, and from which they are ready to be expelled or set free. So that if Gerlach be correct, the relation of the blood corpuscles to the spleen is precisely the reverse of that which I have stated, and they begin there in great quantities ; and it thus becomes important to inquire whose opinion is the correct one. But if my experiments upon the behaviour of the blood corpuscles in the spleen have no other consideration, this merit, at least, remains to them, that they accurately set forth the anatomical facts, and in this manner have already sufficed to refute such false theories as that of Gerlach. In point of fact, Gerlach is altogether wrong when he supposes that the golden yellow granules are changed into blood globules ; for this can in no way be proved, but very easily the contrary. He is equally in error in adducing, as a ground for this view, that blood corpuscles begin as cells in the embryonal liver,—a statement which is altogether incorrect. And when he finally adduces that since, according to Harless †, the blood corpuscles are destroyed by the alternating influence of nitrogen and carbonic acid, a second kind of solution of these in the spleen cannot be conceived ; it need only be remarked that this theory of Harless's is not in the least proved as regards the living organism. So, also, Virchow ‡ has expressed himself as partially against mine and Ecker's account; since, though he does not at all doubt the dissolution of blood corpuscles, yet he altogether denies the origin of cells around

* Loc. cit.

† Ueber den Einfluss der Gase auf die Form der Blutkugelchen : Erlangen, 1846.

‡ Archiv für pathologische Anatomie und klinische Medicin, Band i. SS. 452. 483.

heaps of blood corpuscles. This statement is only explicable by supposing that the Mammalia and Reptilia, in ~~whom~~ this phenomenon can be seen as plainly as could be wished, were not examined by Virchow. Besides, I do not maintain that the effused blood always forms cells containing blood corpuscles; only I hold it as a fact established beyond all doubt, that this very frequently happens in the spleen as well as in extravasations in the lungs, lymphatic glands, brain, and thyroid body; and while I believe that the formation of cells around these several effusions is not an equivalent fact, yet it is altogether certain that blood globules enclosed in cells undergo a more speedy dissolution than if they remain free.

In conclusion, one word concerning the import of the changes of the blood corpuscles in the spleen. It may be asked, whether they constitute a normal and physiological, or a pathological appearance? On the one side, very weighty grounds may be alleged for the normal character, especially their (so to speak) *constant* occurrence and innumerable quantity in such a number of animals living in their natural condition, as the amphibia and fishes were. Furthermore, the apparently complete health which existed in spite of the vast quantity of dissolving blood globules. Thirdly, in Reptilia, the cells containing blood corpuscles may be seen in bloodvessels which are in no way isolated from the general circulation. Fourthly, similar and constant changes of the blood repeated at short intervals are absent from other organs of birds, mammals, and reptiles; and many other arguments might be adduced. But, in contrast to these facts, many others appear on a more careful contemplation, which may almost lead to the opinion that all the changes of the blood globules in the spleen are possibly only pathological appearances. In fishes, dissolutions of the blood corpuscles occur not only in the spleen, but in an exactly similar way in other organs, namely in the kidneys, the liver, and the peritoneum. In the first of these organs their presence is *constant;* at least, in the examination of many examples of eel, pike, Coregonus muræna and murænula, Salmo fario, Barbus fluviatilis, Cyprinus brama and carpio, and Tinca chrysitis, not only were they always present, but almost always as numerous as they were observed to be in the spleen. In the peritoneum and the liver they were sometimes scarce, sometimes frequent, but only in the carp and Tinca chrysitis were they constant; in other fishes they were either altogether absent, or only occurred here and there, as in the trout. If to these facts be appended that in certain animals,—to wit, in cats, sheep, and others,—the changes of the blood corpuscles in the spleen are very seldom observed, one can scarcely resist the notion that the appearance is abnormal; and this is much more the case when one considers that similar appearances which are known not to be physiological, constitute almost constant occurrences, and are associated with exactly parallel changes of blood globules. Of this, the small effusions of blood in the lungs, bronchial glands, and thyroid bodies of men, and those of the lymphatic glands and mesentery of pigs and rabbits, are instances. But this latter view is insusceptible of full explanation; for although pathological effusions and metamorphoses of blood often constitute almost a constant occurence, yet, first, the quantity of blood globules which undergo dissolution in such effusions is in no comparison at all with that of the millions which are destroyed in the spleen; and, secondly, it has yet to be shown that effusions of blood may not occur as a physiological phenomenon, as happens in the bursting of a Graafian follicle in the ovary, in menstruation, and in the separation of the placenta. And although all animals do not show in the spleen such a solution of the blood corpuscles as can be verified by the microscope, yet it is by no means proved therewith, that where ~~this~~ takes place it depends on a pathological condition; indeed, the blood corpuscles of different animals may undergo dissolution in different ways. At least thus much is certain, that in all animals, without exception, stagnations of blood occur in the spleen; and I might add, almost of a certainty, in mammals, extravasations also. In these stagnations, the blood globules may dissolve themselves in the one case *rapidly,* in the other case *slowly*, and thus, according to the outer phenomenon, a *difference* will be produced. Such an occurrence may be *physiological,* since it is, at least in many animals, visibly *constant* and very extensive; and it may have the greatest signification to the life of the organism. Therefore, so long as the pathological character of the phenomenon is not proved of a certainty, I am disposed to hold fast by its physiological nature, and to consider the dissolution of the blood corpuscles in the spleen as a normal fact.

6. *Bloodvessels of the spleen.* — The *splenic artery* (*arteria lienalis*) springs from the cœliac axis, and courses with many windings between the layers of the gastro-colic ligament until it reaches the fundus of the stomach, where it enters the gastro-splenic ligament, after giving off some small twigs to the pancreas and the stomach. Arriving in the neighbourhood of the hilus lienalis, it divides into a superior and an inferior branch. The upper of the two, passing somewhat upwards, and giving backwards from two to six short arteries (*vasa brevia*) to the large extremity or pouch of the stomach, divides into from three to six branches, which, lying in a line one over another, extend to the hilus, into which they enter. The inferior branch is somewhat larger than the others; it passes to the inferior and anterior part of the spleen, supplying it with three to six branches, which enter the hilus in the same manner as the others, and it ends finally as the gastro-epiploica sinistra. Thus, all the six to twelve branches which enter the spleen lie tolerably

in one line upon each other in the gastro-splenic omentum, and they are also connected to each other by fat and areolar tissue. The size of the splenic arteries is very considerable in proportion to that of the organ, and so also the thickness of their coats is worthy of notice. In the first of these respects, it is possible that only the thyroid gland exceeds the spleen; the liver, which is so much larger than this organ, being supplied by an artery of scarcely larger size than the splenic, although we must not overlook the fact, that beside this the liver receives very much additional blood through the vena portæ. In the mammalia generally, the splenic artery is proportionally smaller than in men; this possibly depends only upon the more considerable contraction of the vessel at their death. Wintringham finds that the thickness of the arterial coats is greater than that of the aorta above the giving off of the renal arteries, to which it bears the ratio of 1 to 0·762; he also states that they will sustain a pressure of 41 lbs.

The serous covering of the spleen receives some unnamed small arteries: thus a twig is given to it from the left inferior phrenic artery, which courses in the phrenico-lienal ligament; and, besides this, it receives branches from the first lumbar, from the left spermatic, and from the splenic itself. Additionally to these, in some of the vertebrata, to wit in the calf, small twigs in great number leave the substance of the spleen, and after perforating the fibrous coat of the organ spread themselves out upon its surface.

The *splenic vein* altogether corresponds in distribution to the splenic artery. So many primary arterial branches enter the hilus of the spleen, and just as many veins come out of it. These six to twelve veins unite into two branches, and receiving, the upper the venæ breves from the stomach, and the lower the vena gastro-epiploica sinistra, they constitute the trunk of the vein. In the spleen, and at their emergence from it, the veins lie anterior to the arteries, but then they place themselves posteriorly to them; and it is behind the arteries that they unite to form the common trunk. This trunk receives a twig from the pancreas, from the lymphatics of the spleen, from the stomach, and, further, the vena coronaria ventriculi; it then passes away over the aorta to the under surface of the liver; and, finally, with the vena mesenterica superior it constitutes the trunk of the vena portæ.

The splenic vein, like all the branches of the vena portæ, has no valves, and is the largest branch which assists to form that trunk. Its width is very considerable: according to E. Home* and Giesker, the proportion to that of the arteries is as 5 to 1; and according to earlier authorities it is yet more. The proportionate size of the branches is still larger; and, according to C. A. Schmidt, their ratio in the spleen itself to that of the arteries which run with them is as 20 to 1. In contrast to this, the thickness of their coats is very inconsiderable, and, according to Wintringham, is to that of the arteries as 1 to 4·8 or 4·3, to that of the iliac vein as 1 to 3·5.

On their entry into the spleen, both arterial and venous branches receive as a covering a process of that "tunica propria" of the spleen which forms the *vaginæ vasorum*, previously described.

These are not alike in all animals: thus, for instance, they differ in man from those exhibited by the higher brute mammalia — a fact which explains the various descriptions given by different authors. In man, the sheaths of the vessels form *complete* coats around them. A section made in the centre of the hilus, and continued through the spleen, exhibits them very distinctly as projections or processes of the tunica propria, and also allows their further circumstances to be seen. It is thus shown that arteries, veins, and nerves are thickly enclosed in these sheaths; but in such wise that they are easily separated and isolated, especially in old, or macerated, or boiled spleens. The arteries and nerves allow of this more easily than the veins, which latter have a closer connection to these sheaths. It is further seen that not only are the trunks of entering and emerging vessels thus covered, but that their finer ramifications receive a similar clothing. The thickness of these sheaths is in the human subject by no means inconsiderable. As Giesker correctly states, they are at first exactly the thickness of the tunica propria, and retain the same thickness for a considerable distance, that is, as long as they clothe the main trunks of the vessels. On the branches which proceed laterally from these trunks, and on their further extent, the sheaths become naturally finer, and gradually increase this fineness as the vessels become more minute, until finally, becoming very delicate, they lose themselves in the pulp of the spleen in the manner previously mentioned. The thickness of a sheath is always less than that of the coat of the artery which it incloses, and greater than that of the vein; yet this does not hold good of vessels in all parts of their extent, since on the finest branches the sheaths are proportionally somewhat stronger than on the larger ones. As to the relations of the sheaths to the rest of the spleen substance, it must especially be considered that they do not lie free in the parenchyma of the organ, but are connected with the general trabecular network by means of balks which are given off from them: but these balks are not so numerous as different anatomists appear to think; so that we are scarcely entitled to consider with Giesker, that the whole trabecular network is formed out of this connection.

In other Mammalia, as in the horse, ass, ox, pig, sheep, &c., the course of these sheaths differs in some respects from that seen in man. In the three latter animals, which in this respect are best known to me, no

* On the Structure and Uses of the Spleen, Phil. Trans. for 1808.

sheaths at all are found on the smaller veins, and on the larger they are chiefly found on that side on which the arteries and nerves which accompany them lie. Only the two primary trunks of the veins which proceed from the spleen have for a very short distance a complete sheath, while all the arteries, even the finest, possess one; a condition of which more will be said hereafter.

The minute structure of the sheaths of the vessels in man altogether correspond with that of the partitions; and this holds good of animals generally. But I have not been able to detect unstriped muscular fibre in the sheaths in all those cases in which I have found it in the trabeculæ. In oxen this is especially the case; while, on the contrary, in pigs, &c., they are very plainly present.

Great difficulties oppose the inquiry concerning the distribution of the vessels in the spleen itself: since, 1stly, injection or inflation of the vessels gives little result on account of the delicacy of the organ; and, 2dly, great difficulties are connected with the microscopic examination of the organ. What will be now adduced concerning it is especially the result of the latter method of inquiry, which, combined with fine preparations by the knife, has seemed to me to be the most fertile in results.

When the main branches of the splenic artery have entered into the spleen they lie in their sheaths, each in company with a vein, to which they are posterior and inferior: they are in tolerably loose connection with the sheath, and not unfrequently they take a serpentine course. In their further distribution they do not behave as arteries generally do, which continually give off smaller branches, but they divide immediately into a quantity of different large and long branches in the manner of a shrub; of these the larger branches go to the anterior, the smaller to the posterior, margin of the organ. Beside this, it is especially to be remarked of the arteries of the spleen, that their different branches form no anastomoses. Assolant tied a branch of the splenic artery in a living dog, and then allowed the spleen to return into the cavity of the belly. The dog died thirty hours after: much inflammation and exsudation of a bloody serous fluid was found in the belly, and the spleen was quite healthy; only the part cut off from the circulation of the blood was gangrenous, and, as it were, separated from the sound part by a line of demarcation. In contrast to this, Heusinger tied all the branches of the splenic artery, one only excepted; upon dissection, the whole spleen was found to be mortified, excepting the part in which the artery not deligated ramified. Also injections in an artery always return solely by the corresponding branch of vein; and they only fill that region of the spleen in which the branch ramifies, never passing over into any other. I am unable from my own experience to pass any judgment upon these data, and will therefore not impugn them; but I may be allowed to doubt whether the capillaries of the pulp are completely separated from each other, and am more inclined to believe that, in consequence of the anatomical circumstances of the pulp, such a separation must be considered as impossible; since in the spleen we have before us, not a gland with special lobes separated from each other, but a parenchyma everywhere united. The above results of deligation and injection by no means necessarily imply an isolated course of the capillaries, and are fully explained by the supposition that the arteries possess no anastomoses.

When the arteries have divided into small vessels of 1 to 2-100ths of a line, they come into contact with the Malpighian corpuscles in the mode already described; while they are also connected to these by their sheaths. According to Giesker, their final terminations are coronal or pencil-shaped, radiating so as to surround the Malpighian corpuscles, and altogether enclose them; then arriving at the highest point of the vesicle, they return upon themselves in the shape of a loop, course back again as veins, and there meet together, beneath the point whence the artery radiated, to form a vein, which enters the same sheath from which the artery emerged. At this point the sheath divides into three to four fibrous threads, which pass over on the spleen corpuscles to the threads arising nearest to them, and unite with these. If we compare with this description of the minute anatomy of the spleen that which is considered most admissible by J. Müller, the next author after Giesker, we shall find very considerable contradictions. J. Müller finds that the smallest branches of arteries partly continue on the side of the corpuscles without giving off branches to them, partly perforate either a portion or the whole of the corpuscle, without in any instance leaving any branches of the artery in its interior; that these fine arterial branches pass through the middle of the corpuscles, then continue on their coats, and then quit them altogether; and that if an artery in the corpuscle divides into many branches—which never happens on the surface, but always in the thickness of its coats — these branches leave it again, in order to ramify minutely in the surrounding red pulpy substance of the spleen, into which part especially all the fine pencil-shaped ramifications of the arteries pass. The commencements of the veins spring from these branches; they are tolerably large, anastomose frequently with each other, and scarcely have a special coat as yet. If a little piece of the pulp of the spleen be carefully examined, it will be seen that it is as if cribriform, and constitutes as it were a network of red partitions, the diameters of which are larger than the interspaces and canals existing between them. It is these venous canals which give the cellular appearance seen in inflation of the veins of the pulp, and which, injected, form structures resembling the corpora cavernosa of the penis. Special cells or cavities do not exist.

So far J. Müller. If we now ask ourselves the reason of these important differences between these two authors cited, one of whom affirms the continuation of the tufts in the pulp, and a connection of Malpighian corpuscles with arteries and venous interstices only; while the other denies all this, we shall find it not very difficult to give an answer. Giesker, in his description, limited himself to the appearances met with in the human subject, while J. Müller made the pig and the ox the basis of his delineation. This circumstance will at least partially explain the want of correspondence in the two descriptions; for I find that between the spleen of man and that of the animals mentioned considerable differences exist.

In *man*, at least generally, the arteries together with the veins pass deeply into the substance of the spleen, lying in the same sheath with them, and exactly following their course. According to Giesker, the two classes of vessels accompany each other even to their final ramifications; but this is not correct. In every spleen instances occur, which are easily seen, where small veins and arteries lie very close to each other; and Giesker has evidently allowed himself to regard these particular instances as the rule, and has extended it as a description to the smallest branches of vessels. But if an arterial and venous primary branch be successively followed to their minutest ramifications, it will be seen that, sooner or later, every artery and vein, without exception, separate from each other, and follow their special path. It is not at all unusual to find this even with arteries from ½ to 1 line in diameter, but it is always the case with those of from 1-10th of a line. In such an instance the artery, setting out alone, does not perforate the sheath in which it hitherto lay, but takes with it a distinct yet often inseparable covering of the same; so that from this point forwards a special and separate venous and arterial sheath exist. And in man the Malpighian corpuscles lie only on these isolated arteries; a state which Malpighi and Müller had already described in Mammalia.

As regards the other circumstances of the arteries, I have found them exactly as Müller describes them in the lower animals. After the smaller branches of the arteries are connected with the Malpighian corpuscles, they enter into the red spleen substance, and immediately upon this each small trunk spreads out in the shape of a tuft into a large number of yet finer arteries (*fig.* 526, *d.*); and these tufts or pencils of arteries, lying in great numbers close to each other, give to the terminations of the arterial trunks a very beautiful appearance, which may be best compared to the broad crown of a (*pollard*) tree. These separate tufts, dividing and diminishing in size yet more, terminate by an immediate transition into the true capillaries; which, in a more and most minute form of 3 to 5-1000ths of a line, constitute a close and beautiful network in the separate portions of the pulp, and in those parts of it which surround the Malpighian corpuscles; although they do not form a special vascular covering for the same. Many authors seem to deny the existence of capillaries in the spleen: thus Engel * has lately altogether denied them; but this is quite erroneous. They may easily be seen in the pulp of the human spleen, by the aid of the microscope, both empty and filled with blood, and exhibit themselves as in no way different from the capillaries of other organs; and the finest of them have a diameter of only 3-1000ths of a line. J. Müller is also in error when he describes the arteries as coursing through the coats of the Malpighian corpuscle, since they always pass on its exterior. Finally, Giesker is wrong in describing the arterial pencils as spreading themselves out on the Malpighian corpuscle, and here becoming continuous with the veins; even in man it is not difficult to discover that the pencils only begin beyond the corpuscles, that they lie in the pulp, and that it is here they first break up into capillaries.

Giesker at least partially agrees with this statement when he says † that the pulp consists of nothing but the minutest arteries and veins united by fibrous tissue. The sheaths of the vessels above described are just as much more delicate as are the vessels themselves, and they are finally lost as distinct coats on the capillaries; here they form delicate fibrous membranes which connect the capillaries together, and under this form they pass through the whole of the pulp.

As to the *veins*, I must first, with Giesker, express myself in the most decided manner against all the more ancient and modern anatomists who suppose and describe venous spaces (*sinus venosi*) in the human spleen. I have bestowed the greatest attention to the dilated commencements of the veins in question, and it was only my own researches that led me to renounce the opinion that these dilatations really exist; indeed I have never been able to discover anything special or extraordinary about these veins. Firstly, as to the larger veins, which are as yet accompanied by the arteries, there is nothing very remarkable about them, with the exception of their considerable size, which has been already mentioned. They all have a membrane which is continuous with that of the smaller veins, and is least separable on that side with which the artery is in contact; this membrane is only distinguishable from the sheath of the vessels by its greater delicacy, and in company with this sheath it gradually diminishes its thickness. Orifices of the smaller veins, constituting the so-called stigmata Malpighi, are present in very small numbers in the larger veins; while, on the other hand, they are somewhat more frequent in the smaller of the vessels in question. When the veins

* Zeitschrift der Gesellschaft der Aerzte in Wien, 1847.

† Loc. cit. S. 166.

leave the arteries and pursue their way alone, they vary in some respects from this description, although not so considerably as might be imagined from the delineations which have been given of them. In the first place, the character of the branchings is peculiar, since from hence onwards, and so much the more frequently the smaller the veins become, branches are given off from the veins on all sides at very nearly right angles, and the open mouths of these ramifications are seen from within as numerous round or oval orifices lying very closely to each other. In the second place, the membranes of these veins gradually become thinner and thinner, and at the same time are blended with the similarly attenuated sheaths, so that both constitute only one delicate membrane, which is nevertheless everywhere demonstrable even in the smallest vessels which can be isolated, and which everywhere exhibits itself without any interruption as a perfectly continuous membrane. Dilatations or pouchings can nowhere be seen, either in the course of the isolated veins or in their smallest branches; only it must be added, that the narrowing of their calibre occurs much more slowly than in the arteries. As to the beginnings of the veins, and their connection with the capillaries, I have not been able to detect anything more than what one sees elsewhere; namely, that by a constant simplification and attenuation of their structure, the veins finally pass into capillaries. Here also no traces of dilatations are visible, of whatever kind these dilatations might be imagined to be; and there is just as little appearance of any other peculiarity.

As regards *the brute mammalia*, many of them certainly correspond in a very considerable degree with man, in respect of the condition of these vessels; but my researches do not extend sufficiently to enable me to express myself decisively on this point. While, on the other hand, some, as the horse, ass, ox, pig, and sheep, exhibit essential differences. In the latter animal, which I have examined the most carefully, the following deviations are present. The arteries differ little from those of man, only they separate earlier from the veins to pursue their isolated course. In most other respects they behave precisely as J. Müller has described them, and as I have also spoken of them in man; only I cannot corroborate the statement of Müller, that the sheaths of the smaller arteries are equal in strength to those of the greater. The ramifications which reach the Malpighian corpuscles measure from 1 to 1½-100ths of a line in diameter; they then course in the pulp, form very beautiful tufts, and finally capillaries, of which the smallest measure from 3 to 4-1000ths of a line. But in contrast to this, the veins exhibit very essential differences. In the first place, a special membrane and sheath are only found in the largest venous trunks, and even here they only extend a short distance around the circumference of the vessel; while more deeply in the spleen they only lie upon the side where the artery and nerve are attached to the vein. In all the smaller veins which are no longer accompanied by arteries, there is no trace of these two membranes to be seen; and not only is this the case, but the mode in which the precise limit of the venous canal is indicated is also very extraordinary. The vein appears to be formed in the first instance by the strong anastomosing trabeculæ, and soon afterwards it seems composed simply of delicate fibres and red substance deposited between them, a structure which continues even into the large venous trunks. They thus distinguish themselves at the first glance as excavations in the parenchyma of the spleen, which are devoid of walls. Nevertheless, by a more careful examination of the red limits of these veins, one may verify their smooth and shining appearances, a circumstance which is significant of the existence of a delicate membranous covering; and, in point of fact, microscopic investigation proves the existence of an epithe-

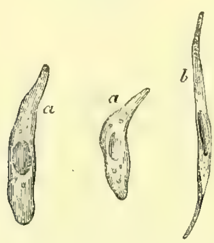
Fig. 534.

Epithelial cells from the Splenic vein of Man and other Mammalia. Magnified 350 *diameters.*

lium, which every where clothes this surface, and consists of fusiform or more spherical cells, of ½ to 1-100th of a line in diameter, with roundish or elongated nuclei of 3 to 5-1000ths of a line in size (*fig.* 534.). This epithelium altogether corresponds with that which covers the part of the veins possessing a visible membrane; but in the vessels of which I am speaking, it is placed in part immediately on the trabeculæ, in part upon a delicate fibrous membrane limiting that part of the pulp which bounds the veins. In consequence of what has been said, the greater number of the splenic veins of the ox must be likened in respect of their structure to the spaces in the corpora cavernosa penis, and to the sinuses of the dura mater; since, instead of the venous membranes elsewhere present, they possess only the "*tunica intima*" in the shape of a delicate epithelium. So that one may speak of them as "*venous sinuses*," and the more correctly, if it be considered that these veins, almost devoid of walls, possess a colossal width, and are everywhere rendered quite cribriform by larger and smaller veins opening into their interior; which smaller veins may themselves be traced by their great width for a considerable distance. How these smaller veins are connected with the very distinct capillary network of the pulp, I have not been able to find out; and I do not believe that either injection or inflation of the vein, or a microscopic examination, will ever give any definite conclusion hereto. For these vessels, often possessing but a few little trabeculæ for their coats, are of such a delicate texture, that they tear by the slightest mechanical force, while by the microscope they cannot be distinguished from the surrounding constituents of the pulp. Yet thus much one may see, that the veins gradually become very small,—so small, that it is quite impossible to talk of their commencing as dilated spaces. For my own part, I am convinced that a similar communication obtains between the veins and capillaries of oxen as of men; and that the only possible difference is, that the veins here possess only an epithelium, and must therefore be connected with the capillaries in a somewhat different way. I will yet further add, that in microscopic examination of the pulp of animals, skeins of epithelium are not unfrequently found, consisting of roundish cells, as it were, fused together: these can only come from the small venous trunks.

The following may be noticed concerning the microscropic structure of the splenic vessels: —The arteries everywhere possess their three usual coats. The *inner* consists, first, of an

Fig. 535.



Epithelial cells from the human Splenic artery. *a*, shorter cells; *b*, somewhat longer cells.

epithelium of spindle-shaped cells, which easily come off in skeins or separately (*fig.* 535, *a*, *b*); and, secondly, of an elastic membrane of homogeneous composition, wrinkled in the longitudinal direction (*fig.* 528, *e.*), and with or without openings: which openings although very small, are visible even in the arteries of the tufts. The middle tunic is very thick, and gives rise to the considerable thickness of the wall of the vessel; it contains very little else but unstriped muscular fibres. In the larger and largest arteries, nets of elastic fibre and elastic membrane (*gefenstirte membranen* of Henle) are also present, while they exist without exception on the vessels which pass to the Malpighian corpuscles, and on those which form the pencils or tufts. The adventitious (or cellular) coat is altogether absent from the smaller vessels in the interior of the spleen, and is here represented by the sheath; but it exists in the larger vessels, and presents white fibrous tissue and meshes of elastic fibres. The capillaries (*fig.* 536.) have a simple, structureless membrane, with nuclei lying on its

Fig. 536.

Capillary from the Spleen of the Pig. Magnified 350 *diameters.*

inner surface. The veins have been already described as they exist in brute mammalia: in man they possess—1. An epithelium as above described; 2. A membrane of elastic longitudinal fibres; 3. Transverse unstriped muscular fibres, in a single or double layer, which are present in the trunk of the splenic vein and all its primary branches in the interior of the spleen, but are absent from the smaller and smallest veins; 4. White fibrous tissue, with elastic fibres which take a longitudinal direction. The smallest veins possess only white fibrous tissue with elastic fibres, and an epithelium.

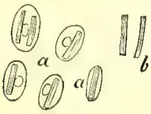
So much has been already said above concerning the blood of the splenic vessels and of the spleen, that I will here only append some special observations made upon animals. In a dog whose spleen abounded in the dissolving blood globules, the blood of the splenic vein distinguished itself by a very great quantity of colourless blood corpuscles, almost all of which contained numerous nuclei, and often had a deceptive resemblance to pus globules. In the blood of the liver were found a great number of altogether different blood

Fig. 537.

Blood corpuscles from the liver and Splenic vein of a Dog, with yellow crystals of a substance resembling Hæmatine.

globules (*fig.* 537.). These were swollen out and almost colorless, but contained from 1 to 5 thinner or thicker small rods of a dark yellow colour; part of these possessed the same length as the blood globules, part were shorter. These small rods were unchanged in water, but in acetic acid they seemed to disappear. In a second dog I found the same cells with small yellow rods in the blood of the splenic vein, while they could not be detected in any other part of the body. With them I found at the same time numerous colourless blood globules with manifold nuclei. In the fresh-water perch, the blood of the splenic vein of many individuals contained numerous golden yellow cells with diminished blood globules. In the same blood, and in the splenic pulp, there also occurred, either sparingly or in uncommon quantity, rod-shaped crystalline corpuscles, of a yellow colour, and a length of 4 to 6-1000ths of a line : at the first glance they seemed to be lying altogether free, and they were dissolved by potash (*fig.* 538, *b*). On the application of water a membrane was upraised from these

Fig. 538.



Similar blood corpuscles from the Spleen and Splenic vein of the fresh-water Perch.

a, crystals and nuclei seen on treating colourless nucleated blood corpuscles with water; *b*, crystals apparently free.

small rods, and near them a nucleus came into view (*fig.* 538, *a*). On more accurate inquiry, it plainly appeared that these small rods lie in decolorized blood globules, and in unchanged blood globules the gradual formation of one, or even two, of these may be followed. In *Barbus fluviatilis*, the spleen pulp contains an enormous quantity of really free crystals; these are of a violet and reddish colour, and of a nail or spindle-shaped form ; and on the application of acetic acid, they are completely dissolved, leaving some colour behind. Crystals such as these also occurred sparingly in the kidneys, the liver, and the blood of the heart. In this animal, as well as in *Cyprinus brama*, the blood contained yellow granule-cells, like those which occur in the spleen and kidneys. All the rod-shaped yellow corpuscles just named (of which the first, indeed, are nothing but crystals) must in any case consist of a substance allied to the hæmatin of the blood ; and possibly they consist of the substance which Virchow has lately named hæmatoidin, with which they correspond in some respects. Their occurrence in the spleen is physiologically interesting, and so also is their formation within the blood corpuscles, while at the same time it affords a very plain indication of the relation of hæmatin to them.

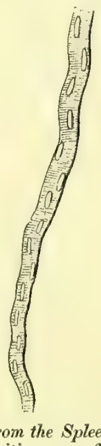
7. *Lymphatics.*—The views of authors concerning the lymphatics of the spleen are very contradictory, since one class have the precedent of Haller for altogether denying their existence in the human spleen, while others have stated their existence in abundance, and have constituted the spleen, in a certain measure, a large lymphatic ganglion. This difference mainly depends hereon,—that the one class have specially examined the human spleen, while others have chiefly drawn their conclusions from that of the lower animals, considerable differences in respect of these vessels existing in different creatures. In man, the lymphatics of the spleen are, at any rate, in utterly inconsiderable quantity, being rather less numerous than in other glandular organs, as the liver and kidneys, and not at all so numerous as in the lymphatic glands. They are divisible into superficial and deep. The former course, in sparing numbers, between the two coats of the spleen, and form in this situation delicate trunks, which anastomose with each other ; but, excepting in perfectly healthy spleens, and *in the neighbourhood of the hilus*, they can scarcely be recognised. The latter lie in sparing numbers in the hilus, and in the sheaths of the vessels, where they accompany the arteries, although they cannot be traced so far as there. Both sets of these vessels pass to the gastro-splenic omentum, to enter the small lymphatic glands placed there ; and finally they collect to a trunk which opens into the thoracic duct, at about the eleventh or twelfth dorsal vertebra. All these lymphatic vessels can only be thus seen in the quite fresh and undeteriorated spleens of executed criminals or subjects killed by accidents, although they may often be recognised in particular parts of the healthy spleen after natural death, especially if the vessels be tied and the spleen soaked in water. But, on the other hand, in diseased spleens it is very rare to see even a trace of them, unless a preparation be made of a small gland in the gastro-splenic ligament, in which case small entering and emerging trunks may be recognised.

In the lower animals, or at least in many of them, the lymphatics seem to be more numerous. Moreschi distended the lymphatics of the spleen in fishes (in whom they possess no valves) from the trunk, and he says that the injected spleen appeared to consist almost solely of a network of absorbents. But in another place he freely states that the spleen consists, so to speak, of nothing but vessels. In a *Testudo mydas*, Tiedemann and Gmelin saw all the absorbents of the small intestine going to the spleen, in which, by interlacing with arteries and veins, they formed a network. From this network large branches, like the emergent vessels of the lymphatic glands, took their course towards the thoracic duct. Almost all the older writers recognised the richness of the spleen in lymphatics, which later examiners have but confirmed. But it will be well to set forth one fact which, in my opinion, is not sufficiently estimated, namely that *even here* absorbents are *only sparingly present in the interior of the spleen ;* at least I have found this to be the case in the pig, ox, sheep, &c. Here the superficial lymphatics are, as is well known, very numerous, and this fact seems to me to correspond with the circumstance that in these animals the serous and fibrous coats are only loosely connected to each other, and contain many vessels in the loose areolar tissue between them. But, on the other hand, if the vessels in the hilus be examined, only a few scattered trunks can be seen, a condition which stands in extraordinary contrast with the very numerous lymphatics of the coats. Thus, for instance, in the hilus of a large calf I found only four trunks of lymphatics, which together possessed a diameter of only 176-1000ths of a line; while the interior of the spleen is also poor in lymphatics, for, so far as I have seen, the numerous plexuses of lymphatic trunks in the coats of the spleen have no relation with the interior of the organ, but at least the greater number of them belong solely to the subserous areolar tissue.

As to the distribution of the lymphatics in the spleen, it may easily be seen, by observations on oxen, that they only follow the course of the arteries, lying with these inside the sheaths; while the veins, which take a solitary course, and (as was before mentioned) possess no sheath, are also devoid of these companions. I have not seen the commencement of the lymphatics, yet I can state for a certainty, that they have nothing to do with the Malpighian corpuscles, since these corpuscles are completely closed, as was before mentioned. And, I will add, in support of this my view, that the small arteries which pass to the Malpighian corpuscles are no longer accompanied by lymphatic vessels; at least microscopic examination detects no trace of such vessels within their sheaths. Just as little does the pulp possess any lymphatics; for if these, like the nerves (see below), pass from the sheaths of the arteries into the pulp, they would in such a case be visible. And from what has been said, I conclude that the lymphatic vessels of the interior of the spleen belong wholly and solely to the sheaths of the arteries, and not in the least to the pulp or the Malpighian corpuscles; and thus that here they play precisely the same rather subordinate part which they do in the liver, where they pertain to the capsule of Glisson, and not to the glandular substance; or as in the kidneys, in the interior of which they only accompany the bloodvessels. Concerning the structure of the lymphatic vessels, I can only state thus much; that in the calf they possess, at least in their main trunks, three membranes: — 1. An epithelium similar to that of the arteries; 2. A circular fibrous membrane, composed of two or three layers of very distinct unstriped muscular fibres; 3. An outer membrane of white fibrous tissue. Valves occur in the deep as well as in the superficial lymphatics.

8. *Nerves.* — The nerves of the spleen arise from the splenic plexus, and accompany the splenic artery as two or three interlacing trunks, and divide in such wise at the giving off of its branches, that each artery receives one, or very frequently two nerves, which accompany it, and here and there anastomose with each other. The thickness of the primary nervous trunks varies very much in different creatures. Thus in the sheep, and especially in the ox, they are of really a colossal size, and taken all together, their diameter equals that of the empty and contracted splenic arteries; while in man and the pig they are no way remarkable in size, and are many times smaller than the arteries. These differences, which led the earlier authors to speak of the splenic nerves in similarly different expressions, were at first altogether inexplicable to me, since I could not understand why the spleen of one animal should possess so much larger nerves than another. On a more careful examination, the microscope gave a very simple and unforeseen explanation. The uncommon size of the splenic nerves of Ruminantia depends solely on this, — that the white fibrous tissue of these nerves is disproportionally developed in the shape of the so-called "fibres of Remak," while it is much less prominent in the same nerves of other animals. A comparison of the splenic nerves of the pig and calf has taught me that if we limit our inquiry to the number of primitive nerve fibres, scarce any difference exists between the two sets of nerves. But, on the other hand, the primitive nerve fibres of the pig lie very closely together, so that they cannot be numbered without considerable trouble; while as an example of their condition in the calf, I will adduce the following: — The trunks of the nerves entering the hilus were seven in number, with a diameter of ·57, ·2, ·048, ·6, ·48, ·48, ·6 (line); and they contained respectively only 28, 7, 6, 9, 13, 9, 22 primitive nerve fibres. In the lower animals, the nerves may be followed with the knife for a considerable distance into the spleen, much further than in man; and with the help of the microscope, I have very frequently followed them even on the arteries which go to the Malpighian corpuscles. I have been just as little able as Remak to find any ganglia on the arteries in the interior of the spleen. Concerning their mode of termination, I am only able to say thus much; that the nerves also pass into the pulp, and may even be easily seen on the pencils of arteries, and finally that they disappear as very small branches of not greater size than the smallest capillaries; but I am unable to decide whether they terminate by means of

Fig. 539.



A very small nerve from the Spleen of the Calf, without any visible primitive nerve fibres, and apparently consisting only of neurilemma (or fibres of Remak). Magnified 350 *diameters.*

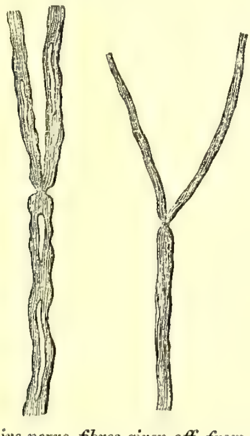
loops or with free extremities. In the calf, the thickness of these smallest nerves on arteries of a line in diameter (where it is not uncommon to find two such trunks) is 24 to 28-1000ths of a line; on the pencils of arteries 48 to 56-10,000ths; on the smallest arteries and capillaries 3 to 4-1000ths. Their structure was so far peculiar, that in the calf the finest nerves (*fig.* 539.) exhibited no trace of nerve fibres, even when treated with soda and acetic acid, but they seemed to consist wholly and solely of the fibres of Remak. Nevertheless, in branches of 12 to 28-1000ths of a line, I have often very plainly seen a single

Fig. 540.

A somewhat larger nerve, in which may be seen a single dark nerve fibre: also from the Calf. Magnified 350 *diameters.*

nerve tubule of 20 to 28-10,000ths of a line (*fig.* 540.), with dark margins, in the midst of the fibres of Remak. From these facts it may be concluded that the finest nerve tubes in the spleen of the calf are devoid of the dark borders, just as they are in the organ of smell according to Todd and Bowman; or as in the Pacinian corpuscles, the cornea, &c.; but we are scarcely able to conclude therefrom that they possess the same constitution in the adult animal. I will here permit myself to

Fig. 541.



Two primitive nerve fibres given off from the trunk of the splenic nerve of the Calf, about an inch before its entry into the Spleen. Magnified 350 *diameters.*

add an interesting microscopic observation concerning the splenic nerves of the calf. A *division* of the *primitive nerve fibres* takes place in them (*fig.* 541.), similar to that which Henle and myself found in the Pacinian corpuscles, Müller, Brücke, and R. Wagner in the muscles, and Savi and R. Wagner in the electrical organ of the torpedo. But what is *altogether new* in the minute anatomy of nerve is, that these divisions do not take place at the terminations of the primitive nerve fibres, but *in their trunks.* I detected them in the large trunks which accompany the splenic artery previously to its entering the hilus; and, indeed, in considerable numbers, so that I often counted three or four such divisions in one preparation. They always took place by the division of a primitive nerve fibre at an acute angle into two parts, and never gave rise to more fibres. These divisions often repeated themselves on the same fibre, so that in one instance three, and in another case even four, fibres were given off by the successive divisions of a single primitive fibre: this happened in the smaller branches in the interior; but, so far as I could remark, it did not occur in the smallest branches of nerves, although, from the difficulty of examining the finer nerves, I cannot say that such divisions were absolutely wanting here. The signification of these facts seems to be very important, both in an anatomical and physiological point of view, but this is not the place to give a more detailed statement. But thus much will I remark: that by means of such a distribution of the nerves, a small nerve may be rendered subservient to a larger organ; and, in addition, an harmonious activity of the whole organ may be facilitated; while, finally, in respect to sensation, it may possibly explain the want of an exact local sensibility.

In concluding this treatise on the anatomy of the spleen, I will allow myself *briefly* to propound somewhat concerning the physiological and pathological *properties* of the organ.

The spleen is developed at the end of the second or the beginning of the third month, in the fœtal mesogastrium at the fundus of the stomach. It originates from a blastema which is developed independently in this situation, and neither proceeds from the intestine, like that of the liver, nor from the pancreas, as Arnold has maintained; since, although in the ruminants it is placed on this gland, yet in the dog, according to Bischoff, it is not. It is at first a small, white, often slightly lobulated corpuscle, which gradually reddens, and soon becomes as rich in vessels and blood as it is in the adult. The elements of the fœtal spleen are originally quite uniform cells; at a later period part of these are transformed into fibres and vessels, while part become persistent as the parenchyma-cells. It is only subsequently that the Malpighian corpuscles are developed, yet I have found them, without exception, both in man and animals, at the end of the fœtal life. According to Heusinger, the proportion of the spleen to the whole body is, in an embryo of ten weeks old, as 1 to 3000; in the eighth month it is, according to Huschke, as 1 to 720; while at birth, he states it to be as 1 to 357; in the adult as 1 to 235 to 400; and in old age as 1 to 600 to 800. From these data it will be seen, that the proportionate weight of the spleen to that of the whole body increases very rapidly in the embryo, and is almost as great at the period of birth as in the adult; from which it sufficiently follows, that the spleen is an organ, the activity of which extends from the end of the fœtal period through the whole life, and reaches its highest point in middle age.

As regards the *function* of the spleen, of the innumerable theories and hypotheses respecting it, only a very few deserve a nearer consideration; namely, only those *which place the spleen in intimate relation with the life of the blood.* In point of fact, almost all the facts which with greater or less certainty we know concerning the spleen, and, above all, the anatomical ones, point to such a relation. Hewson had already stated, that when an organ receives more blood than it requires for its own nutrition, we may conclude therefrom that that blood undergoes a change in it, or a secretory process takes place; and this expression will not apply to any organ in the body better than to the spleen, which must be considered as relatively better supplied with blood than any other organ. Therefore since all pathological, anatomical, and physiological facts prove a relation of the spleen to the blood, we may securely assume, that a change of the blood takes place in the spleen. The only difficulty is to know what change. Firstly, the blood may either suffer a change in its transition from the arteries to the veins; or, secondly, the separation of a particular lymph from the blood may take place in this organ. It is well known that the latter view was first maintained by Hewson *, who at the same time announced that the lymph generated in the spleen serves to form blood corpuscles; and since then, Tiedemann and Gmelin have specially supported the same view. But the grounds adduced for this theory seem to me to be insufficient. At one time, the great quantity of lymphatics in the spleen was brought to prove that a special lymph was developed here. But that part of the spleen on which special stress is laid, namely, the interior or parenchyma, is quite poor in lymphatic vessels; and its surface, even in the lower animals, scarce contains more of such vessels than other organs; to wit, the peritoneum covering the liver, the pleura covering the lungs, &c. Therefore the formation of a special lymph by the spleen can as little be assumed as in the case of the lungs and liver. Secondly, the red colour of the spleen-lymph, and its greater coagulability, have been adduced as proofs of a peculiarity, and of a blood-forming import. But it may be demanded, are these properties constant, and on what do they depend? As to the first question, it is certain that a red colour of the spleen-lymph is, on the whole an *exception*, as Seiler and Ficinus * formerly stated. In rabbits, cats, or dogs, I have never found such a colour, and have also always found the chyle of the thoracic duct of only different shades of white. But I will not deny that in calves and sheep a reddish spleen-lymph is often found, and I will add that this is frequently the case in the horse. But this is sometimes the case in other organs, as, for instance, in the liver and in the lacteals, where Tiedemann and Gmelin in some cases also found a reddish and very easily coagulable fluid; and it is important to observe, that the reddish colour and easy coagulability in these cases depend simply on blood which is mixed with the lymph. Thus, if the reddish spleen-lymph of a calf be examined, a quantity of fully developed blood corpuscles are found in it, which are altogether identical with those in the blood.† Now since it cannot be assumed that real coloured blood globules are formed in the lymphatic vessels of the spleen, and since, in point of fact, all trace of such a developement of blood globules is absent, it will only follow from the facts adduced, that in the cases of reddish spleen-lymph a mixture of real blood and lymph has taken place. This mixture may be the result of normal anastomoses between lymph and bloodvessels, or may owe its origin to a rupture of both these vessels. I believe the latter to be the case, and am simply of the opinion that it is not at all to be wondered at. For in Tiedemann's cases the animals were either killed by a blow on the head, or died during convulsions; and it is not surprising that during such a death-struggle an organ so richly supplied with blood as the spleen should make an abnormal path for that fluid, or that a similar thing should happen when the vena porta has been tied. It is well enough known, how easily the lymphatics of the spleen are filled by an injection into the bloodvessels. The reddish colour and easy coagulability of the spleen-lymph in particular cases therefore proves nothing at all, except that, on account of its great vascularity, blood is more easily extravasated in the spleen than elsewhere, and enters the lymphatic vessels. Thirdly and lastly, Tiedemann and Gmelin adduce the above-mentioned course of the lymphatics in the tortoise as a powerful proof of their view; but Rudolphi ‡ found exactly the contrary, since in two large sea-tortoises not a single lymphatic of the intestine passed to the spleen, but they all went directly to the thoracic duct.

In consequence of what has been said — which I might also corroborate by many other facts could I go more into detail — it is impossible to imagine the development of a special lymph in the spleen; and hence the

theory which ascribes to the spleen a relation to the lymphatic system, and considers it as in a certain manner a large lymphatic gland, is utterly devoid of meaning. In this manner there remains as a last resource the view, that changes occur in the blood itself contained in the spleen. But what is the nature of these changes? Are blood corpuscles possibly formed in the spleen, as has been already so often supposed? Certainly not; for in the most rigorous examination of the blood in the spleen and the larger splenic vessels, just as in the spleen-lymph, no trace whatever of the formation of blood globules can be detected, much less in blood which is exactly reversed, and is exhibiting, as I might say, at every step the plainest and most lively indications of a dissolution and decomposition. Let us recall to mind the details already given of the condition of the blood globules in the spleen. Upon the facts there mentioned, in the year 1847 * I founded the conjecture that the blood corpuscles *undergo solution in the spleen, and that their colouring matter is employed in preparing the colouring matter of the bile;* a conjecture which seems to me preferable to all those which have hitherto been offered concerning the function of the spleen. If the fact be made out that new blood globules are continually arising from the cells of the chyle, it is just as certain that the blood globules must also slowly disappear in order to make room for those newly arising. And if it be considered that nobody has yet seen the least trace of a solution of blood globules in any other organ, and that, on the contrary, I have found in the spleen a healthy organ, in which, in all four classes of vertebrate animals, blood corpuscles are almost constantly undergoing decomposition, even in uncommon quantities, it will, I think, be conceded to me that I have some grounds for setting forth the hypothesis here given. It is, indeed, as yet not altogether settled whether the changes of the blood seen by me are normal or abnormal; but, as was previously remarked, so long as their pathological nature is not proved with certainty, I must continue to regard them as physiological and pertaining to healthy life. But this is not saying that they occur in all creatures in the method described above. It is highly possible that blood globules undergo dissolution in the spleen without previously forming the cells containing blood corpuscles: an opinion which is corroborated by the blood globules described above as occurring in the blood of the splenic vein of the dog and fresh-water perch: these contained crystals of hæmatine or some kindred substance, and were evidently near their destruction. Indeed, it is even possible that such a direct mode of dissolution may be the rule in some animals, perhaps even in many. And although I have regarded the spleen as an organ in which the blood corpuscles undergo dissolution, yet I have not maintained therewith that it is in all animals the *only* organ in which any thing of this kind occurs: it would therefore in no way militate against my theory if it should ever turn out that in the kidneys of fishes, the vessels of which are arranged so peculiarly, a constant and physiological solution of blood globules obtained. The following circumstances also speak for my hypothesis. That in no other way can any reasonable account be given of the changes of the blood in the spleen. Furthermore, that it elucidates the relation of the spleen to the portal system of veins; since according to it, the dissolved blood corpuscles are subservient to the formation of the bile, the colouring matter of which is so nearly allied to that of the blood. Finally, that, as will be more fully stated below, the pathological facts are proportionally in unison with it.

On all these grounds I am therefore inclined to defend the hypothesis first set forth by me of a destruction of the blood globules in the spleen; and the more so, that J. Béclard has lately maintained, that the blood of the splenic vein is always poorer in blood corpuscles than that of the other veins. He has stated this in a memoir which was laid before the Académie des Sciences in Paris on the 17th January, 1848, and published in the "Archives générales de Médicine" of October to December, 1848. Since J. Béclard's results are an important support to my hypothesis, I have permitted myself to communicate here the most important of them. Béclard has analysed the blood from the lower branch of the splenic vein, and that from the jugular vein, in fourteen dogs and two horses. In most of the instances of the analysis, (1.) the water, (2.) the blood corpuscles and fibrine, and (3.) the albumen and salts, were separated from each other; and only in the horses were the blood corpuscles and fibrine obtained separately. A deficiency of the blood globules and fibrine was always present in the splenic vein, which diminution out of a 1000 parts of blood, amounted to the following quantities in the sixteen cases.

16·54	15·94	8·51
37·11	19·67	13·06
19·43	20·80	14·91
12·82	10·88	9·40
13·92	16·06	
13·60	14·78	

On an average of the sixteen cases, the deficiency amounted to 16·08 parts. As regards the albumen, on the contrary, there was a constant increase of this constituent in all the sixteen cases, in an average of 13·02 parts. Finally, in the two analyses in which the quantity of fibrine was certified, there was the extraordinary increase in its quantity in the blood of the splenic vein of 0·3 and 0·5 parts. Béclard deduces the same conclusion from these facts which I have drawn from my microscopical examinations; namely, that the blood corpuscles normally undergo dissolution in the spleen; and I regard this conclusion as neither more nor less correctly deduced than

* Loc. cit. S. 135.

mine, for it is clear that the results of his analyses may solely depend upon this fact, that in the animals he examined, the changes which I have verified in the blood globules of the spleen, were going on in an energetic manner. If these visible changes of the blood globules, — which certainly occur in a most exquisite manner in the horse and dog,—if they be normal appearances, then is the diminution in the quantity of the blood globules, which Béclard found on analysis, also a normal phenomenon; but if not, then he only examined a blood partially deprived of its globules by stagnation and effusion. The results of chemical analysis would then only be secure, if it were at the same time shown, that there were no visible changes of the blood globules in the spleens of the animals examined. Until this takes place, Béclard's conclusion will remain, like mine, hypothetical; although this is in no way diminishing the merit of his observations, since I hold my own hypothesis as one which I am perfectly justified in propounding in the present state of our knowledge. But even if we suppose that the blood corpuscles are destroyed in the spleen, it is nevertheless a question how this dissolution is super-induced, and at what time it comes to pass. As regards the first of these points, in my writing previously mentioned I expressed the opinion, that the spleen is a contractile organ, and may, by virtue of its contractility, be able to dilate and contract itself, — to fill itself with blood, and again to expel the blood from it. In the state of filling itself with blood, a stagnation of blood occurs in the smaller vessels, perhaps even an extravasation; and in this stagnant blood, the blood globules undergo destruction, since they slowly dissolve themselves, either free or inclosed in cells. This view I still regard as correct. For, firstly, it is a matter of fact that the spleen does enlarge and diminish its size, and certainly under vital circumstances which are altogether normal. Very many of the older observers have accepted this fact; as Lieutand, Haller, Stuckeley, Rush, Clarke, Hodgkin, Home, and Dobson. This is shown by an examination of the splenic region in the living human subject (Piorry). So also it is shown by vivisection of animals, in whom I have myself seen (and especially in the dog) a very distict diminution and rounding of its outer surface. Finally, Landis *, by weighing the spleen, has recognised a distinct increase and diminution of weight. He examined at different times thirty rabbits, and finds that the average weight of the organ in five observations was:

12	hours	after eating,	0·768	grammes.†
5	„	„	·588	„
8	„	„	·548	„
24	„	„	·526	„
48	„	„	·510	„
2	„	„	·444	„

Now although it may be freely conceded that an organ like the spleen is subject to so many variations in respect of size as to render thirty observations much too small a number to afford any very definite information concerning its increase or decrease of size, it must, nevertheless, be considered, that Landis has examined the proportion of the spleen to the whole body, and to many other organs, as the stomach, liver, and kidneys, and that from this means he derived a confirmation of what the estimate of its absolute weight had previously taught; so that his observations must be regarded as a meritorious contribution to our knowledge respecting the changes of volume which the spleen experiences. We now ask, secondly, how these changes come to pass? Béclard states that the spleen enlarges and becomes filled with blood in consequence of the splenic vein being compressed by a muscular force; but the nature of this he has not stated, nor can I regard his view as correct. I believe myself to have propounded a better theory when I stated, that the spleen becomes turgescent in consequence of the relaxation of the muscular fibres which exist in its balks, coats, and vessel-sheaths; or in animals from whom these are absent, through a relaxation of the muscular fibres of the vessels themselves. A constriction of the splenic vein cannot be supposed to obtain, since the muscular fibres which it contains are but very little developed, and no other compressing force is present; while, on the contrary, we know that in all animals the splenic artery is uncommonly muscular, and that the partitions of the spleen themselves contain distinct muscular fibres. It is these muscles and no others which, according to my researches, produce the distension of the spleen; but not through their contracting together, but by their relaxation, which brings with it a distension of the vessels with blood, and a slower circulation of this fluid. The diminution in the size of the spleen occurs simply through the contraction of the muscular parts just named. Precisely in the same manner the corpora cavernosa of the penis become filled with blood by a relaxation of the muscles situated in their fibrous partitions; and become poorer in blood, and smaller in size, when the muscles again contract themselves. Of course, both here and in the spleen, the nerves play an important part in the process; probably in consequence of antagonistic relations between them and other parts of the nervous system, which at present cannot be accurately indicated. Thirdly, and finally, it may be asked, whether the blood corpuscles simply dissolve because the blood of the spleen becomes stagnant at certain times, or whether special influences are necessary to this effect? — whether the parenchyma of the spleen or the Malpighian corpuscles may not secrete a juice, a "*succus lienalis*," of which the earlier authors speak, which exerts a solvent influence on the blood corpuscles? As a kind of vague answer to this question, I have examined the parenchyma with respect to its

* Loc. cit.

† The "gramme" is $15\frac{1}{2}$ grains Troy English. (Transl.)

reaction, and have found that without exception it has an energetic *acid* reaction. This appeared to me very extraordinary, and the more so when I thought of the great quantity of blood which the organ contains; and I was already captivated by the conjecture that this acid reaction might be of great importance. But I found that litmus paper was just as much reddened by the liver and kidneys of the calf and rabbit; and, further, that the muscular substance of the heart and the muscles of the trunk have the same effect. So that this acid reaction appears to be a general phenomenon, which is probably due to the fact, that the acids lately found by Liebig in muscle (lactic and inosic acids) also occur elsewhere. At any rate since there is as yet no exact chemical analysis of the spleen, I cannot express myself concerning the import of this vigorously acid reaction of its parenchyma; although it is very conceivable, that the acid reaction does not depend on the same causes in all organs.

As regards the time at which the blood globules experience their dissolution in the spleen, nothing definite can at present be said; but my theory appears at least to presuppose, that this process especially comes to pass some time after the reception of nutriment, since I have found the spleen of the greatest size in animals at about the time of five to twelve hours after eating, the same time at which the visible changes of the blood globules were most marked. The cause of this phenomenon seems to be, that the volume of the blood is increased after each time of taking food, and especially that a great number of new cells enter from the chyle. And if an equal weight is to remain in the organism, then, on the other hand, just as many elements of the blood must be dissolved, as there have new ones entered into it; and this is exactly what happens in the spleen. Besides, I am not anxious to maintain that the spleen may not become distended, and blood globules undergo dissolution, at other times than those just mentioned; probably the conditions of the liver have also a great influence upon the events in the spleen, so that in hyperæmia of the liver, the spleen becomes also distended; and so likewise the nervous system may be interested therein. Béclard, who has also found many variations in the blood globules contained in the blood of the splenic vein, is unable to assign any definite cause for these varieties, and only remarks, that in the case of a blood rich in blood globules, the amount of these lost in the spleen was greater than in the opposite case. So that it must be left to the future to bring to light the more special relations of the dissolution of the blood globules in the spleen.

I have hitherto said nothing concerning the function of the Malpighian corpuscles of the spleen. I do not regard their function as at all a peculiar one, since (1.), in many animals, as fishes and naked amphibia, these corpuscles are absent; 2. their constituents exactly correspond with those of the parenchyma of the spleen. I believe that the parenchyma-cells and the cells of the Malpighian corpuscles play exactly the same part, although I am just as little able as my predecessors to say with certainty what this is. If they are not subservient to the formation of a special fluid which takes a part in the solution of the blood corpuscles, I should be almost inclined to ascribe to the parenchyma-cells the mechanical use of forming in the first place a soft parenchyma in which the minute vessels can extend at their pleasure; and nextly, that they, as well as the elements of the Malpighian corpuscles, are simply expressions of the fact, that the spleen, as a highly vascular organ, is everywhere permeated by a fluid which is very rich in plastic matters. At the same time, it may be imagined that all these cells elaborate the fluid in which they are soaked, and after a certain kind of assimilation, again part with it, and through the blood and lymph vessels transmit it to the general circulation. The swelling up of the Malpighian corpuscles after the use of food is quite consonant with this notion. But whether this fluid is of a peculiar nature, and of different properties from that of other organs, we can only know from future chemical researches; and then only can it be determined, whether or no we are to ascribe to it a special signification.

If the spleen be the only or even the chief organ in which blood globules undergo their dissolution, in either case the part which they enact in the organism is by no means the subordinate one which many have hitherto considered it; but one which is very *full of import*. And the results afforded by vivisections and by pathology are by no means so contradictory to this expression as they are generally maintained to be. It is true that the spleen of animals may be excised without causing their death, a fact which I have myself repeatedly witnessed; it is also certain, that men can live without spleens, or with spleens completely atrophied, or rendered functionally useless by degeneration; nay, in many cases, may live without any disturbance at all,—a circumstance which is also true of animals. But what does this prove? Nothing at all; for if the spleen fails, then indeed other organs undertake its functions, and discharge them vicariously for it. Probably in these cases the blood globules undergo dissolution in the general mass of the blood, or possibly in the liver. But if this be so, the spleen is surely not therefore devoid of import or function. With equal correctness might we say, that one kidney is superfluous, because in certain cases an hypertrophied kidney enacts the part of both; or might regard kidneys generally as devoid of import, because certain rare instances of misdevelopement are narrated, in which the skin or the thoracic glands have undertaken the excretion of the urinary constituents. If the spleen is not the only organ in which blood corpuscles undergo dissolution, it is possible that these are destroyed in some small quantity in the capillaries of all the organs of the body.

Many observers, as Lecanu and Letellier, and more recently J. Béclard, have found a diminution in the quantity of blood corpuscles in the venous blood generally, although others have denied this. If this be the case, it confirms such a supposition, and would effectually explain the results of extirpation. In any case thus much is certain, that they afford no grounds for regarding the spleen as devoid of signification. Finally, we may remark in addition, that not unfrequently extirpations of the spleen give rise to considerable disturbances, and especially of the biliary secretion; a fact which very well corresponds with my supposition that the colouring matter of the bile arises from the hæmatin set free in the spleen.

If this theory of the function of the spleen which I have set forth, which Ecker has adopted, and which J. Béclard has now confirmed, be correct, it will be able to explain the diseased conditions of the spleen and their operation on the organism. But this is at present impossible, since these conditions are much too little known to allow us to say anything even approximatively correct and secure concerning their origin and import. Therefore, instead of entering upon a discursive detail of possibilities resting upon an altogether hypothetical basis, it seems to me much more suitable, simply to indicate the points to which future observers might properly direct their special attention. It is known that the enlargements of the spleen, which constitute the most serious diseases of the organ, have a special coincidence with complaints in which either a dissolution, or some other abnormal condition of the blood is present. This is the case in typhus, typhoid cholera, pyæmia, putrid exanthemata (erysipelas, scarlatina, measles), dyscrasia of drunkards, ague, scurvy, purpura, chlorosis, acute rheumatism, acute tuberculosis, &c. May not the enlargement of the spleen possibly have a share in the production of these diseases, without being so entirely secondary as most pathologists have hitherto assumed? Is it not conceivable, that in a spleen which is enlarged and distended with blood, a destruction and dissolution of the blood globules is going on on too large a scale, so that the normal composition of the blood becomes seriously prejudiced thereby? In such a case the blood would be poorer in blood globules, but its plasma would be rich in colouring matter, and possibly at first in fibrine, as J. Béclard found it to be in his analysis. May not chlorosis or scurvy, in which a considerable diminution of the blood corpuscles has been shown to exist, possibly depend in part on the disproportionate activity of an enlarged spleen? In consequence of such a too considerable destruction of blood globules in other cases, further changes of the blood may be induced, which may then end as an overcharging of the fluid with colouring matter; to wit, with the colouring matter of the bile; or as a pyæmia or the so-called white blood. On the other hand, is it not possible, that in cases of the temporary diminution, or inflammation, or degeneration, or atrophy of the spleen, other organs may undertake its functions?—as, for instance, the liver, which, indeed, is usually hypertrophied in such cases; or the general mass of blood, a state which must again give rise to peculiar phenomena? Thus, in respect of its pathology there is much which might yet be observed, if I did not consider it more suitable to conclude with the remark, that in order to the building of a larger superstructure upon the anatomical and physiological basis here given, and in aiming at anything respecting the pathology of the organ, a deliberate, careful inquiry is above all things necessary, an inquiry in which chemical analysis, microscopical research, experiment, and pathological experience, will have to go hand in hand. For if I have perhaps been able to elucidate the spleen in many respects more correctly than my predecessors, yet this account is very far from a final termination of our knowledge, and must be regarded as nothing more than a foundation-stone for an altogether new superstructure.

Morbid Anatomy. — Variations in number and form have already been alluded to. The absence of the organ is usually or always accompanied by that of other and neighbouring viscera.

On account of the obscurity which has hitherto attached to the anatomy of the organ, its diseased conditions are little understood; and it is obvious, that until morbid conditions of the spleen are examined and classified with reference to the appearances of their several anatomical constituents, there will be little to be said under the head of morbid anatomy, besides enumerating the most prominent deviations of its bulk, colour, and consistence.

Enlargement of the spleen is, perhaps, the most common of all the outward deviations. We have already seen that, within certain and very wide limits, the size of the spleen may vary, and that these wide variations are of constant occurrence even in the healthy subject, being intimately associated with its function and that of the organ. It is, therefore, only when such enlargement becomes excessive, or is associated with an alteration of texture, or occurs in the course of some of those diseases which it is known usually to accompany, that we are justified in regarding it as essentially morbid.

The enlargement of the organ, to all outward appearance, depends mainly on the increased mass of the contained blood, and is hence sometimes called hyperæmia; and the most obvious distinction of this enlargement is into two kinds:—one in which the congestion is produced mechanically; the other, in which the determination of blood to the organ can only be accounted for on the supposition of non-mechanical causes. The former of the two classes would include the swollen spleens which occur in obstructions of the portal vein, or of the vena cava, as happens in some diseases of the liver and heart respectively.

In such instances, there is little appearance of any thing morbid beyond the increase of size. The contained blood is usually very dark, and the spleen shares the deepening of colour. By long duration, the capsule of the organ and the fibrous tissues generally, become somewhat thickened, but in other respects the texture is little altered. In the second class, in which the swelling is probably produced by a peculiar state of the blood (*dyscrasia*), and is certainly associated with a class of blood diseases, the texture of the organ is usually much altered. The size of the spleen is often astonishingly increased, so that it possesses a volume of from 100 to 300 cubic inches, and a weight of 10-20 lbs. The increase includes, besides blood, a considerable quantity of a fibrinous material, the nature of which, and its relations to the healthy organ, are at present little known. The colour and consistence are of every possible gradation; from greyish to deep brownish red, or from a soft, friable mass, to a dense, firm, and almost fibrous texture. There is a general relation of these changes to the date and duration of the swelling; thus in acute or recent cases, the organ is usually soft and of a dark colour, while by long continuance, or in chronic diseases, its consistence is greatly increased, and its colour, as well as that of the contained blood, is much paler or greyer than natural. *Atrophy* of the spleen, or slow and permanent diminution of its size, is much more infrequent than the preceding converse condition. It is associated with similar varieties of colour and consistence.

Inflammation of the spleen.—The peritoneal surface of the organ shares in the diseases of this structure generally, and an inflammation of this part of the serous membrane not unfrequently accompanies the enlargements previously mentioned. The exsudation and results are no way peculiar. Concerning inflammation of the parenchyma of the spleen little can at present be said. The large and numerous veins which it contains are liable to inflammation, the secondary being the more frequent form of phlebitis which affects them.

As regards other morbid products, organised and unorganised, the spleen offers nothing deserving a special notice.

STATISTICS, MEDICAL. — *The Statistical Method; the Numerical Method. La Méthode Numérique.* — It is to be regretted that the use of numbers in any branch of scientific inquiry should have seemed to need a special name; for the name has given rise to prejudices and misconceptions which could never have attached to the thing signified. There is no science which has not sooner or later discovered the absolute necessity of resorting to figures as measures and standards of comparison; nor is there any sufficient reason why physiology and medicine should claim an exemption denied to every other branch of human knowledge. On the contrary, they belong in an especial manner to the class of sciences which may hope to derive the greatest benefit from the use of num-

* The Editor is indebted to his friend Dr. Brinton, for the translation of the article on the normal anatomy of the spleen from the German MSS. of Professor Kölliker, and for the sketch of the abnormal anatomy.

bers; and even those persons who are most given to express doubts of the necessity or expediency of resorting to them, find themselves constrained to sanction by their own practice what they condemn in theory. This is an all-sufficient answer to those who content themselves with objecting in general terms to the employment of numbers in medical investigations. As to more minute and detailed objections, these will be found to be anticipated and disarmed by the simple consideration that they apply in reality not to the use, but to the abuse of numbers. The time has long gone by, when the absolute dependence of all science on observation and experiment could admit of question or dispute; and, as no one in the present day claims for physiology and medicine any immunity from the severe conditions which the very nature of things imposes, we are spared those appeals to authority which might formerly have been required at our hands. The absolute necessity of observation and experiment towards the improvement of the science and art of medicine, in the widest acceptation of those terms, may, therefore, be safely taken for granted. The only points upon which any serious difference of opinion or divergence of practice exists, are the degree of care and accuracy which should be brought to bear on individual observations and experiments, the properties which fit single facts to be thrown into groups or classes; the language which ought to be employed in expressing the general results of such classifications; and the number of facts which, being so grouped or classified, may be required to establish a general proposition, or to furnish an accurate test or trustworthy standard of comparison.

The human mind is so constituted, that it looks forward to an occurrence with a confidence proportioned to the number of times that it has been previously known to happen. Hence, the universal belief that all living beings will die, and that the sun will rise and set to-morrow; hence, the somewhat less sanguine expectation that quinine will cure ague, and that vaccination will either prevent or modify small-pox; hence, the little hope we have that a severe attack of Asiatic cholera will terminate favourably, and our absolute despair of the recovery of a patient seized with hydrophobia. In these, and other analogous cases, we have either the experience of all mankind in all times and places, or that of large numbers of men in addition to our own. We do not require that the individual occurrences which have created our confidence, our misgiving, or our despair, should be committed to paper, arranged in columns, and embodied in sums or averages. For practical purposes we are satisfied with our own impressions. But should a doubt be expressed, and supported by a show of reason or experience, whether vaccination possess the virtue generally attributed to it; should some new preventive measure or mode of treatment be recommended in cholera, as superior to other plans previously adopted; we ask for the specific facts which have seemed to warrant the doubts of the one party, and the recommendation of the other. If these facts are few, we naturally view them with mistrust, and are disposed to attribute them, at the best, to some coincidence; or if, being more in number, their actual amount is stated in vague and general terms, we as naturally demand the precise figures. We feel instinctively, that common and familiar words are altogether wanting in precision; that they take their meaning from the character of those who use them; that, in a word, "the *sometimes* of the cautious is the *often* of the sanguine, the *always* of the empiric, and the *never* of the sceptic; while the numbers, 1, 10, 100, 1000, have but one meaning for all mankind."

But this mistrust of vague generalities of expression, is not the only form in which the more cautious and logical spirit of modern times embodies itself. The same misgivings are felt and expressed as to the propriety of committing the facts which are to serve as the materials of our theories to the uncertain keeping of the memory. We feel that a science built up of such materials, bears to true science the same sort of relation which tradition bears to history. It may not be destitute of valuable truths and sound principles, but it must fail in that precision and delicacy of discrimination which forms the peculiar attribute of true science as of true history. The history of medicine abounds with examples of important principles of treatment, and valuable remedies discovered solely by the light of experience, based upon the mere recollection of a number of individual occurrences. In this way the efficacy of bark and arsenic in ague, of mercury in syphilis, and of iodide of potassium in certain forms of secondary disease was discovered. Indeed, it may be confidently affirmed that all our knowledge of remedies is traceable to this source; and it is probable that we shall continue to be indebted to it for all future discoveries of importance. It is the natural method of discovery, and, as such, will necessarily maintain its ground. But a very little reflection will convince us of the utter inadequacy of this method to meet the strict requirements of the science, and the ever-varying exigencies of the art of medicine. We may be able by its aid to sketch the broad outlines, and mark the salient points of a science, but we cannot hope to fill in the details with all the lights and shadows which go to make up the perfect landscape. Still less can we satisfy ourselves or others as to the real merits of disputed questions by an appeal to unwritten or loosely recorded experience. We all feel that there is no solution for our doubts short of an appeal to observations carefully and faithfully recorded, and summed up in the clear and simple language of figures. The use of mercury in syphilis, supplies us with an apt illustration of this truth. An experience, founded upon unrecorded and unnumbered occurrences, first recommended this remedy for the treatment of that disease; but it would appear that a counter experience of the same kind was continually leading to its disuse. Thus Morgagni tells us that, when he was quite a young man and went to Bologna, both methods of using mercury, internal and external, were so far deserted, that he never saw any physician make use of them, or ever heard of his using them, for the whole space of eight years, during which he studied there.* It would also appear that from the beginning of the sixteenth century up to the present time, there has always been a large number of surgeons, who have either abandoned the mercurial treatment altogether, or have restricted the use of the mineral to certain exceptional cases.† In the difference of opinion which prevailed upon this subject, the necessity of submitting the question at issue to the test of figures made itself so strongly felt, that a series of the most elaborate inquiries was undertaken at the instigation of governments, or by private individuals. These inquiries resulted in the collection of nearly 80,000 facts, by means of which the possibility of promptly healing venereal sores without mercury and with but moderate risk of a relapse, or of the occurrence of secondary symptoms, was conclusively established.‡ To this same test of figures, all the questions which arise from time to time, as to the relative value of the several remedies recommended in the treatment of syphilis are, by common consent, submitted. A most convincing proof that the numerical method is, in all cases of doubt and difficulty, the means of solution to which men naturally resort, is afforded by the treatise of Benjamin Bell, on this very subject, published in the year 1793.§ Speaking of the treatment of incipient chancres by caustic, he notices the very important objection, that the cure of the sores was often succeeded by buboes; and he adds, that for a considerable time he was induced to suppose that the swellings of the glands, which thus take place after the cure of chancres, were more the effect of accident than of the method of treatment, and that they would have occurred under whatever management the sores might have been. The frequency, however, of their appearance, led him at last to suspect that he was mistaken, and further observation made it obvious that this was the case. He goes on to observe, "As experiment alone could determine the question, I was resolved to employ this test. Of the first twenty patients who occurred with incipient chancres, in ten they were destroyed by an immediate and effectual application of lunar caustic, the remedy being employed, according to my usual custom at that time, instantly on my being called; of the other ten, five were dressed with blue mercurial ointment, and five with common wax ointment. The sores to which caustic were applied healed much sooner than the others, and next to them the sores that were dressed with mercurial ointment. But of the ten patients to whom caustic was applied, no less than eight had buboes, whilst only one bubo occurred in all the others; and it happened in one of the patients whose chancres had been dressed with mercury. I thought also that buboes appeared to be less frequent from the application of caustic, where mercury had been previously given. This fell within my observation from time to time, with patients who had taken mercury, either of their own accord or by the advice of others; and appearing to be of importance, I was resolved to bring it likewise to the test of experiment, and the result was as follows: of forty-eight patients with chancres in an incipient state, and exactly as they occurred in practice, one half was treated in the manner I have mentioned, by destroying the chancres with caustic immediately on my being desired to see them, while all the others were put under mercury for eight or ten days before the application of caustic. In every other circumstance the method of treatment was the same. The difference, however, surprised me exceedingly. Of the twenty-four treated with the immediate application of caustic, twenty were seized with buboes; while only three buboes occurred in an equal number to whom mercury had been previously administered."

The subject of the treatment of syphilis has been selected for illustration on account of the large use which has been made of figures in discussing the relative value of the two modes of treatment; and the extract from the works of Benjamin Bell as a proof that, long anterior to any discussions among medical men as to the value of the numerical method and the extent to which it might be applied in the solution of medical questions, men of shrewd common sense were driven to the use of numbers, as the natural and only means of solving difficult questions, and setting doubtful or disputed points at rest. Thus much, by way of introduction, the difference of opinion which prevails as to the value of the numerical method seemed to demand.

The numerical or statistical method may be defined as the science which prescribes rules for the bringing together of scattered observations, arranging them in classes, testing their sufficiency in point of number, and deducing from them, when so arranged, average and extreme results, fitted by their very condensation to become standards of comparison and data for reasoning.

The numerical method*, so defined and

§ A Treatise on Gonorrhœa Virulenta, and Lues Venerea. By Benjamin Bell, vol. ii. p. 322.

* The term, *numerical method*, will be used throughout this article in preference to the word *statistics*, or *statistical method*; for, properly speaking, statistics means the science of states (from the German word *staat*, a state), and is therefore synonymous with the terms "political economy," "political science," "social science." The first use of the term statistics has been traced to Achenwal, Professor of History in Göttingen, who, in 1749, published an historical work, in which the phrase *scientia statistica* occurs for the first time. The use

understood, comprises two distinct inquiries, the one relating to the individual facts which form the materials for the calculation of average and extreme values, and the other referring to the averages and extremes themselves. This natural and convenient division of the subject it is proposed now to adopt.

1. *Of facts considered as the elements of statistical inquiries.* — Scientific inquiries are conversant with two orders of facts: — namely, phenomena of varying intensity, and events brought about by a multitude of causes. The first class of facts enters very largely into the science of physiology; the last class constitutes, though not to the exclusion of the first, the mass of the materials by which the practical sciences of medicine and hygiene are built up.

As examples of *phenomena of varying intensity* may be cited the pulse and respiration, the temperature of the body, the secretions of the skin, kidneys, and lungs, the evacuations of the bowels, the weight and stature of the body at different ages, and the muscular development and power of different nations and classes of persons. These phenomena, carefully observed and recorded by the aid of the watch, the thermometer, the measure, the balance, and other instruments adapted to special purposes, become so many numerical values, having the same relation to the averages deduced from them, as the more simple events expressed in units bear to the mean results for which they furnish the materials.

As an example of *an event brought about by a multitude of causes* may be mentioned the event of death, governed, as to the age at which it occurs, by original strength or peculiarity of constitution, good or bad nursing and management in infancy, sex, occupation and habits of life, climate and place of abode, skilful or unskilful treatment in sickness; in a word, by the varied influences which make one man to differ physically from another. This is an illustration taken from the science of hygiene. The alternative of death or recovery from a disease induced by a cause or causes of variable intensity in persons of opposite sex and of different ages, with constitutions modified by the several agencies just specified, and submitted to different modes of treatment, is an example from the practice of medicine. Physiology furnishes illustrations of the same kind in those functions of the body (such as the cutting of the teeth, and the first appearance and cessation of the catamenia) which are dependent for the period of their occurrence on peculiarity of constitution determined by the combined action of the influences already adverted to.

Between these two orders of facts — phenomena of varying intensity, and events brought about by a multitude of causes — there is no other difference but that which is apparent on the face of each, namely, that each individual fact, in the one case, is represented by a variable number, while in the other it is a simple unit. If, for example, we count the pulse of several men at the same age, we shall find that each separate observation gives a different number; but, the event of death or recovery in cases of typhus fever will be recorded as a simple unit. In all other respects the two classes of facts closely resemble each other; for the number of beats peculiar to the pulse of each individual, is as much the result of the concurrent action of several causes, as the event of death or recovery from fever. The original and acquired constitution, towards the formation of which so many causes must have conspired, determines the number of the pulse in the one case, and influences the event of the disease in the other. The two classes of facts are also equally fitted to supply the elements for the determination of average and extreme values; for it is obvious that the mean and extreme numbers of the pulse, in males and females respectively, furnish as trustworthy standards of comparison and data for reasoning, as the average number of men following different occupations who die before any specified period of life, and the greatest age which they respectively attain.

From what has been just stated, it will be seen that all the facts which form the materials for our averages, are phenomena or events brought about by the concurrent action of a multitude of causes. The facts or events with which the physiologist and physician are conversant, are remarkable for the multiplicity of the causes which conspire to produce them. The subject of study is the human frame, with its differences of sex, age, and inherited or acquired constitution, acted upon by the variable influences of climate, occupation, and habits of life, and still further modified in disease by the treatment and regimen which may happen to be adopted. In consequence of the number and diversity of the influences brought to bear upon it, the human frame presents an object of study only less difficult than the human mind, affected by a like number and variety of moral causes, of which the true nature and force have to be unravelled by multiplied observations on the condition of mankind under different circumstances; the aggregate of such observations constituting a great part of the science of statistics properly so called, and bearing to the practical science of government the same relation which pathology and therapeutics, based upon large collections of facts, do to the practice of medicine.

Now this dependence of the individual facts or events with which physiology and medicine are conversant on the concurrent action of a

of numbers as a necessary means of comparison in this work of Achenwal, led men to confound the instrument with the science. Dufau, in his Traité de Statistique, incorrectly derives the term statistics from the Latin *status.*

The meaning attached to the words *statism* and *statist,* in the writings of poets, essayists, and dramatists, bears out the view just put forward of the proper signification of the term statistics. Milton, for instance, speaks of "statists and lawyers," and elsewhere uses the term in the sense of a man having political power and influence. Ford also uses the word in this latter sense. South speaks of persons who called our religion *statism.*

multitude of causes, has been urged as an objection to the introduction of the numerical method into the service of those sciences. It is admitted, that the use of numbers and averages by the astronomer who deals with the more simple relations of matter, such as magnitude and relative position, and by the engineer who avails himself of its more simple properties, such as its hardness, tenacity and elasticity, have contributed to make the science of the one perfect, and the art of the other safe; but it is contended that the use of numbers cannot be extended beyond such narrow limits with safety or advantage, and that medicine and political economy lie beyond these limits. The actual practice of mankind, founded upon an instinctive perception of the necessity of employing figures in the service of the physician and statesman, may be fairly alleged as a sufficient answer to this objection; but a little consideration will serve to show its futility.

In the first place, it is self-evident that the exclusion of figures from the service of medicine, does not bring about the disuse of those very facts and events which are objected to as unfit to be employed as statistical or numerical elements. The physician will still persist in stating and recording the results of his experience. He will still assert that he has *sometimes* observed this symptom in a certain disease, that he has *often* found that remedy beneficial, that he has *almost never* known such and such a mode of treatment to fail. Those who contend for the use of numbers in medicine, merely insist on the necessity of reducing the *sometimes*, the *often*, and the *almost never* to a more correct and intelligible form of expression; and they argue that it is utterly inconsistent to object to the use of facts as materials or elements of numerical propositions, and yet not to censure the use of these same facts as foundations for loose and inaccurate verbal statements. From this dilemma there is obviously no escape. But, though the objection itself is futile, the misgiving of which it is the exaggerated expression is natural and well founded. It cannot excite surprise that the individual facts or events which own so many concurrent causes should be regarded as requiring, on the part of the observer, a greater degree of care in verifying, recording, collecting, and arranging them than would be necessary in the more simple cases already adduced; and that both the facts themselves, and the numerical expressions in which they are embodied, should be viewed with a proportionate degree of distrust. From this moderate and reasonable view of the case, no advocate of the numerical method will be found to dissent. On the contrary, he will seek to strengthen it by giving due prominence to each separate ground of misgiving, and by laying down stringent rules for the guidance and governance of the observer. Before proceeding to detail some of these rules, it may be well to advert to a probable, and, indeed, obvious cause, of the distrust with which numerical data are sometimes regarded. Indiscreet advocates of the numerical method have sought to apply the general results of collections of cases expressed in the language of figures to the treatment of individual cases of the same disease, without making allowance for those differences between case and case which confessedly existed in the collections themselves. They have used a general principle, as if it had been a rigid and unbending rule of action; forgetting that though, as the experience of assurance offices abundantly testifies, the general results obtained from a large number of individual facts may be safely reapplied to an aggregate of facts of the same nature, they cannot be brought to bear on a single case, or on a small number of cases, without the greatest danger. Each case must be viewed in practice, first as a generality governed by some large law of prognosis, diagnosis, and treatment; and secondly, as a specialty demanding a careful consideration of all its peculiarities.

Among the rules which ought to govern the observer in the collection of facts destined to form the elements of averages, there are some of so simple and obvious a nature as to require no discussion. Such are, the previous preparation of some simple and available form of register, by means of which the several facts may be committed to paper at the very time of observation, so that nothing may be trusted to the memory; the careful selection of the facts themselves; the shaping of the inquiries which may be necessary to elucidate those facts as nearly as may be in the same terms; the avoidance as much as possible of such leading questions as would be likely to bias the respondent, when the facts in question, like most of the particulars which make up the history of diseases, are dependent upon testimony; and especially the purging of the observer's own mind of prejudices and preconceptions in respect of the subject of inquiry.

The careful selection of the facts which are to form the materials of our averages is by far the most important of these rules, and one which demands a little further consideration. If we consider the facts we are observing in the light of phenomena, or events brought about by a multitude of concurrent causes, it will be obvious that care will require to be exercised, not so much in verifying each phenomenon or event as that of which we are in search, as in ascertaining that all the concurrent causes or conditions are, or have been, in operation to bring about that phenomenon or event. The absence of a single cause or condition will vitiate the individual fact, and impair or destroy the value of our average results. A few illustrations will suffice to show what is here intended. We are anxious to determine the true average frequency of the pulse in adult males, in a state of rest, and as free as possible from the influence of all disturbing causes; but, either from ignorance or oversight, we count it indifferently in every position of the body, and at all times of the day. In this case, our facts cease to be comparable facts; for it is well known, that both posture and time of day have a remarkable influence on the number of the pulse. Or, to take another case, we wish to ascertain the influence of some employment upon health (say that of the letter-press printer); but we overlook the important fact, that in every printing office, two or three very distinct occupations are carried on, of which the most important are those of the compositor and pressman. Not being fully aware of this fact, and of the wide difference existing between the two employments, we proceed to extract from some mortuary register the ages at death of printers as a class, calculate the average age at death, and then proceed to group the whole class of printers with that large class of occupations carried on in-doors, with little bodily exertion, to which the compositor alone properly belongs, but from which the pressman is, by the nature of his employment, excluded. In this case, we should have been misled by the common name borne by men following two really distinct occupations, and our facts would again cease to be comparable facts. A third and apt illustration is afforded by the Asiatic cholera. We wish to compare two different remedies or plans of treatment; but we administer the one remedy, or adopt the one plan, at the onset of the epidemic, and the other during its decline. Here, again, our facts are not comparable facts; for it is one of the well-known characteristics of this disease, that it is more severe on its first occurrence than during the period of its decline. The same sort of error would be committed, if one remedy were administered in an early, and the other in an advanced, stage of the attacks themselves. The principle which these illustrations are intended to enforce, is the necessity of selecting, as the elements of the same average, facts strictly comparable, or, in other words, brought about by the same combination of causes. Over the intensity with which each cause acts in individual instances, the observer can exercise no control. His province is to ascertain that the same combination of causes is at work to bring about each phenomenon or event. If from ignorance or oversight he fails in this duty, he impairs the value of his facts, and vitiates his inferences in proportion to the number and force of the conditions that he has overlooked or omitted.

In the observation and collection, therefore, of the individual phenomena or events which are to serve as materials for our average results, the first precaution to be observed is, that those phenomena or events should be strictly comparable as regards the combination of causes by which they are brought about; or, as the French statists express it, we must ensure "*l'invariabilité de l'ensemble des causes possibles.*" The frequent omission of this most necessary precaution has given birth to the dogma of Morgagni — *Non numerandæ sed perpendendæ sunt observationes* — and to the most valid objections urged against the application of the numerical method in medicine. For the collection, arrangement, and classification of the facts which are to form the materials of our averages, no concise rules can be laid down. The tabular forms must adapt themselves to the exigencies of each individual inquiry; and must be more or less complicated as the subjects of investigation consist of few or many particulars. In reporting cases, for instance, and in collecting and analyzing those recorded by others, tabular forms embracing many particulars are required; and the preparation of such forms demands unusual skill and care.* The same remarks apply to the collection and classification of recorded experiences and opinions bearing on particular subjects of inquiry †; a numerical summary of authorities favourable and adverse to particular doctrines, constituting what may be not inaptly termed *the statistics of opinion.*

2. *Of the average and extreme results deduced from observation.* — The observer having exercised all due care in the observation of his facts, having grouped together only those events which owned the same combination of antecedents or causes; and having further correctly performed the work of enumeration, has thus obtained certain average and extreme results, which are to constitute standards of comparison and data for reasoning; the question naturally arises — are these average and extreme results sound and trustworthy standards and data, or not; and what are the circumstances which render them the one or the other? Common sense and experience combine to give an authoritative answer to this question. Our average and extreme results are more or less sound and trustworthy, as the individual facts from which they have been calculated are more or less numerous. Where the facts upon which it is attempted to found a general principle, or to establish a standard of comparison, are very few, we are at once conscious of their insufficiency; and the more readily when an attempt is made to apply the principle or standard in question to some important practical purpose. A better illustration of the futility of such an attempt can scarcely be found than the well-known test of Ploucquet. That author proposed to determine whether or not a child was still-born by referring every doubtful case to a standard of comparison, founded upon three observ-

* On this subject the late Dr. Todd, of Brighton, has written a very able work, which may be safely recommended to all who desire to enter upon such complicated investigations. The title of this work is: — The Book of Analysis, or a New Method of Experience, whereby the Induction of the Novum Organon is made easy of Application to Medicine, Physiology, Meteorology, and Natural History; to Statistics, Political Economy, Metaphysics, and the more complex Departments of Knowledge. By Tweedy John Todd, M.D., of the Royal College of Physicians of London, &c. &c. 1831.

† Reference may here be made to a paper published in the 3rd volume of the Journal of the Statistical Society of London, "On the best Method of Collecting and Arranging Facts, with a proposed New Plan of Common-Place Book." By the Author of this Essay.

ations of the relative weight of the lungs and body; of which three observations, one was made upon the body of an immature infant, so that the subjects of the observations were not strictly comparable. Though Ploucquet, in this procedure, offended against two of the most obvious statistical rules, his test continued to be treated with undeserved respect, till comparatively recent investigations on a larger scale had demonstrated the little reliance to be placed upon it.

The most common attention to the ordinary daily occurrences of life would suffice to caution us against such errors as that into which Ploucquet fell. Coincidences of the most startling character are constantly happening to put us on our guard against them. One which occurred to the writer of this article deserves to be put on record. Two cases of congenital absence of the larger pectoral muscle on the same side of the body, occurred, on the same day, among the out-patients of the King's College Hospital. This defect he has never happened to observe within the wards of that Hospital or elsewhere, either before or since. A similar coincidence, though of a less striking character, presented itself in the same institution while the writer was noticing with some care and interest the complexion and physiognomy of patients suffering from pulmonary consumption. His own previous experience, in conformity with the general opinion, had pointed out the fair complexion as that of the great majority of phthisical patients; but the almost exclusive occurrence for several days together of the olive complexion, among patients labouring under that disease, had almost led him to discard his former opinion and that of the best authorities, and to embrace one which, as farther observation convinced him, would have been erroneous.

Games of chance are constantly furnishing striking examples of these coincidences, in the shape of what is familiarly known as a run of good or ill-luck; the same event, favourable or unfavourable, occurring many times in succession, contrary not only to reasonable expectation, but to the results of unerring calculation. On the other hand, the success of the bank, with only a slight calculated chance in its favour, but with a capital sufficiently large to await the inevitable change in the run of luck, vindicates the sufficiency of large numbers of facts. The great annual fluctuations, too, which take place in the balance of the receipts and expenditure of assurance offices, but the ultimate safety of their transactions, when extending over a long term of years and embracing a large number of insurances, serve to enforce the same truth.

The sufficiency for all practical purposes of large numbers of facts, may also be inferred from the remarkable uniformity observed to take place in the annual summaries of events brought about by the continued operation of the same combination of causes. The annual reports of the Registrar-General supply many illustrations of this principle. The illustration best suited to our present purpose, is one drawn from an event removed, by the very nature of the case, beyond the reach of external influences, or only very remotely and indirectly amenable to them; namely, the proportion of male and female births in successive years. In the eighth annual report of the Registrar-General (p. lxi.), a table is given, in which the number of males and females born, to every hundred living males and females respectively, is recorded for the seven years 1839–45. If we substitute 100,000 for 100, the table will read thus.

Year.	Males.	Females.	Excess of Males.
1839	6,498	6,211	287
1840	6,539	6,250	289
1841	6,580	6,289	291
1842	6,564	6,273	291
1843	6,597	6,305	292
1844	6,676	6,381	295
1845	6,622	6,329	293

The largest excess of male over female births, therefore, in these seven years is 295, and the least 287, the average being 291; so that the extreme fluctuation amounts to only 8 births in about 6500, or considerably less than 1 in 800; while the excess or defect above or below the average of 291 is only 4 births, or less than 1 in 1600. If the causes which determine the births of males and females respectively could be assumed to be constant and uniform, these fractional fluctuations would express the divergences due to the insufficiency of the number of observations to express an absolutely true result. The close approximation actually obtained must be held to prove the sufficiency for every practical purpose of results based upon large numbers of observations.

Having thus shown, by two opposite examples, the total insufficiency of small numbers of facts, and the sufficiency, at least for practical purposes, of large numbers of observations, it will be necessary to enter into a more detailed examination of the relative value of numbers of observations intermediate between these two extremes.

From what has been already stated, it must be obvious that the degree of confidence to be reposed in results based upon different collections of facts must vary with the number of those facts; and that, other things being equal, the value of the results must increase with every addition made to that number. But it is only by actual observation, or by mathematical calculations based upon indisputable data, that the precise value of any particular number of facts can be determined. Observation, indeed, is altogether unequal to give more than a vague and general idea of the relative values of small and large collections of facts; so that we must ultimately resort to the mathematics both for authoritative decisions and safe guides. As, however, the large majority of mankind is destitute of that mathematical knowledge and training which is essential to the appreciation of mathematical rules, it is desirable to show, by an appeal to the results of actual observation, the increasing value of increasing collections of facts, as well as the rate of that increase. For this purpose, it is proposed to make use of some observations collected by the writer of this article. Having had occasion, a few years since, to bring together, from the pages of the Peerage and Baronetage, the ages at death of the male members of the English aristocracy, dying 21 years and upwards, to the number of several hundreds, it appeared to be a favourable opportunity of testing the relative values of large and small numbers of facts, as well as of obtaining a rude approximation to a rule or measure of value. The ages at death, relating, as they do, to members of the same class in society, and taken without selection from the successive obituaries of noble families, constitute a collection of strictly comparable facts, well suited to the purpose in view. The following table, which embodies the results of these facts in their bearing on the question before us, has been formed in the following manner: — The several facts were first arranged in groups of 25 each; two successive groups of 25 were then formed into groups of 50; the groups of 50, in like manner, into groups of 100, and so on, till the last totals in the table were obtained. The greatest and least averages obtained from each group of facts were then selected, and, with the range, or difference between them, thrown into a tabular form.

Number of Facts.	Average Age at Death.		
	Max.	Min.	Range.
25	69·40	50·64	18·76
50	66·44	55·20	11·24
100	63·70	56·85	6·85
200	62·38	57·61	4·77
400	61·10	58·24	2·86
800	60·84	59·67	1·17
1600	60·25		

Now, if we assume the true average duration of life among the members of the Peerage and Baronetage, who have attained their 21st year to extend to 60 years (being the mean of 1600 observations), and, for the sake of simplicity, substitute for the decimals in the table the whole numbers nearest to them in magnitude, it will follow that, in making use of the several groups of observations specified in the first column of the annexed table, we may have the errors in excess or in defect which are enumerated in the second column.

Number of Facts.	Error in Excess or Defect.
25	9½
50	5½
100	3½
200	2½
400	1½
800	0½

These figures, then, represent the extreme error which could have been committed, in this particular case, by relying on 25, 50, 100, 200, 400, and 800 facts respectively. But it must be borne in mind, that this collection of facts is one which, from the very nature of the case, is likely to present a minimum of divergence between the averages deduced from the same number of facts; for the several obituaries, from which the ages at death are taken, register the deaths of one and the same class, inhabitants of the same country, and split into family groups bearing a close resemblance to each other. If, instead of a single class, exposed to similar influences, and not admitting of subdivision into smaller classes, we were to take the members of that large section of the community which is generally known as the upper and middle class, with their numerous subdivisions of employment, and class them by fifties and hundreds, we should encounter a much more considerable divergence. The results of such a comparison for the class in question are embodied in the following table.

Number of Facts.	Average Age at Death.		
	Max.	Min.	Range.
50	84·44	56·78	27·66
100	76·24	58·25	17·99
200	73·54	61·50	12·04
400	69·78	63·51	6·27
800	68·67	65·07	3·60
1600	67·93	64·84	3·09
3200	66·38	65·82	0·56
6400	66·10		

If, as in the former case, we take 66 years to be the true average age attained by the entire middle class, reckoning from 21 years of age, and reduce the range in each case to the nearest whole number, we shall have the following divergences.

Number of Facts.	Error in Excess or Defect.
50	14
100	9
200	6
400	3
800	2
1600	1½
3200	0¼

In this instance, therefore, though we begin with 50 in place of 25 facts, we obtain a possible error in excess or defect of 14 years in place of 9½ years. It must be obvious, then, that the errors to which averages deduced from any given number of facts are liable, will vary with the nature of those facts; and that the extent of possible error will bear a certain proportion to the number of the influences which are brought to bear on each unit of each collection of facts.

It must not, however, be forgotten that the figures in these several tables represent only possible errors. It may happen that the first 25 observations brought together may yield an average differing by less than a single unit from the mean of thousands of observations; and there is always a balance of probability in favour of the average even of a small number of facts approximating more closely to the true average than to the extremes. That this is the case will be evident on the most cursory inspection of the following tables, of which the first is founded upon the facts

Average Age at Death.	25 Facts. 72 Groups.	50 Facts. 36 Groups.	100 Facts. 18 Groups.	200 Facts. 9 Groups.	400 Facts. 4 Groups.	800 Facts. 2 Groups.

relating to the duration of life of the aristocracy, and the second on the facts relating to the duration of life of the combined upper and middle classes. For the sake of perspicuity, the average of all the facts in either table is distinguished by a larger type.

These tables speak for themselves. In the first table, for instance, the small number of 25 facts is seen to yield the same average as the total of 1800 facts in no less than 9 instances, or one eighth of the whole number; while in 26 out of 72 instances, or more than one third, the average of 25 facts exceeds or falls short of the average of 1800 facts by only a single unit. In like manner, it appears from the second table, that in 20 cases out of 128, or little less than one sixth, the average of 50 facts coincides with that of 6400 facts; and that in 42 out of 128, or nearly one third, it differs from it only by a single unit. Without entering into a minute examination of the other columns of the two tables, it will suffice to state that the probability in favour of an average of a given number of observations coinciding with the true average increases with the number of observations; so that we are again brought back to the expediency of collecting large numbers of observations wherever it is practicable so to do. In using small numbers of facts to establish data for reasoning or standards of comparison, we are bound to speak with diffidence of their sufficiency, and we ought to regard them rather in the light of probabilities requiring to be strengthened by other probabilities, as weak arguments require to be supported by additional reasons, than as, in themselves, worthy of great reliance. According to this view of the case, we are not precluded from the use of averages drawn from small numbers of facts. The employment of such averages with this proviso is an absolute scientific necessity; for in many instances we are prevented by causes too numerous to specify from bringing together facts by the hundred or the thousand, and yet, were we to reject the smaller numbers as inadmissible, we should be thrown back upon the still more loose and less trustworthy general statements from which it is the province of statistics to rescue us.

An examination of the two foregoing tables, as well as of those which display the extreme variations between the averages derived from the same numbers of facts, will serve to prove the hopelessness of any attempt to establish by observation rules for measuring the relative value of averages derived from different numbers of facts. It must be equally evident that no deductions drawn from observation can enable us to state the actual liability to error of any given number of facts, considered as facts, without reference to their peculiar nature. To determine this liability to error belongs solely to the mathematics.

If, on the one hand, observation is unable to supply us with the means of testing the true liability to error of conclusions based on a given number of facts, considered as facts, without reference to their peculiar nature, it must be evident, on the other hand, that mathematical formulæ deduced from abstract reasoning can only supply us with the means of measuring the value of a given number of facts in this their abstract relation, without taking into account the varying quality of the facts themselves. But as it is of the utmost importance to be able to test the abstract sufficiency of a given number of facts to establish a principle or to supply a sound standard of comparison, it will be necessary to enter at some length into this part of our subject.

The facts already adduced, must have abundantly shown that the limits of deviation from a true average result are wider or narrower as the number of facts from which the average is drawn is smaller or greater. Many eminent mathematicians, and M. Poisson among the number, have laboured to convert this general principle into an exact numerical expression or formula, applicable as a test of the true value of larger or smaller collections of facts, and as an exact measure of the limits of variation. M. Gavarret, in his work on Medical Statistics, contends successfully for the introduction of these formulæ into the service of the medical man; and adopting the sentiment of Laplace, "Le système tout entier des connaissances humaines se rattache à la théorie des probabilités," he insists that medical statistics, or, as we prefer to term it, the Numerical Method, applied to medicine, is nothing more nor less than a special application of the Calculus of Probabilities, and the Theory of large Numbers; and that as such it is the most indispensable complement of the experimental method. In other words, he deems it incumbent on the medical man to apply to his numerical results the corrections supplied by the formulæ of the pure mathematics; and before he concludes that any number actually obtained by observation is a true representative of a fact or law, to determine whether that number may not be comprised within the limits of possible variation. M. Gavarret illustrates the necessity of this precaution by applying his mathematical formulæ to a great variety of results based upon observation; but he especially insists upon bringing the alleged efficacy of certain modes of treatment to this searching test. The most convenient course to adopt, in reference to these formulæ, will be to present the calculations based upon them in tabular forms, and then to apply these calculations to one or two striking examples.

The following table presents at one view the possible errors corresponding to average mortalities deduced from different numbers of observations. It is obvious that the table is equally applicable to other contingencies of the same kind, where one of two events is possible in every instance. The mode of using it will be presently explained and illustrated.

Table of the possible Errors corresponding to Average Mortalities deduced from different Numbers of Observations.*

Number of Observations.	Average Mortality by Observation.	Number of Deaths.	Number of Recoveries.	Possible Error.	Number of Observations.	Average Mortality by Observation.	Number of Deaths.	Number of Recoveries.	Possible Error.

500	0·250000	125	375	0·054772	1000	0·350000	350	650	0·042661

The use of this table will be best explained by an example. Let us suppose that a medical man, having, for a long time, adopted a particular course of treatment in a certain malady, has arrived at the following results:

120 deaths, 680 recoveries, 800 cases.

The average mortality in this case would be $\frac{120}{800}$, or 0·150000 (see the second column of the table for 800 facts and 120 deaths). At first sight the medical observer would appear to be justified in asserting that under his method of treatment the mortality was at the rate of only 150,000 in 1,000,000 patients, or 15 per cent. But this assertion would be immediately met by the objection that the number of facts is not sufficient to justify this statement, that an average deduced from so small a number as 800 facts can only be received as an approximation to the truth, and that it requires to be corrected by the aid of the figures in the table.

Accordingly, on referring to the column of possible errors corresponding to 800 cases and 120 deaths, we find that the error in excess and defect to which this number of facts is liable, amounts to 0·035707, which error must be added to and taken from the 0·150000, the result of actual observation. It follows, therefore, that the true result must be somewhere between the numbers

0·150000 added to 0·035707, or 0·185707, and 0·150000 dim. by 0·035707, or 0·114293.

* This table is an abbreviation of one given at p. 142. of Gavarret's work, but with additional calculations based on the same formula, for the numbers from 25 to 200 inclusive. The formula from which the figures in the column of possible errors have been calculated is,

$$2\sqrt{\frac{2 \, . \, m \, . \, n}{\mu^3}}$$

in which m represents the number of times that an event A has happened, n the number of times that an event B has happened, and μ the total number of events: so that $m + n = \mu$; $\frac{m}{\mu}$ the average frequency of the events m, as obtained by observation; and

$$\frac{m}{\mu} + 2\sqrt{\frac{2 \, . \, m \, . \, n}{\mu^3}} \text{ and } \frac{\mu}{m} - 2\sqrt{\frac{2 \, . \, m \, . \, n}{\mu^3}}$$

the limits within which the true average, as corrected by the formula, lies.

So that instead of asserting, as we should seem justified in doing, that the mortality under the influence of the treatment adopted amounted to 15 per cent., we could only claim a mortality comprised between the numbers

185,707 and 114,293 in 1,000,000 cases:

or approximatively between the numbers, 19 and 11 per cent.

Uncorrected observation, therefore, would give, as the result of the treatment adopted, 15 per cent., while corrected observation would give some number between 19 and 11 per cent.

The application of the formula given in the note to an actual case will be more instructive than an imaginary example.

M. Louis, in his *Recherches sur la Fièvre Typhoïde*, has attempted to illustrate the treatment of typhus fever, by minutely analysing 140 cases. The result was as follows: —

Number of deaths	(m)	52
Number of recoveries	(n)	88
Total -	(μ)	140.

The mortality in these cases was therefore $\frac{52}{140}$, or 0·37143; and if we were to take this mortality as the strict expression of the results of the treatment adopted, we should shape our proposition as follows: — The mortality of typhus fever, under the treatment adopted by M. Louis, amounted to

37,143 deaths in 100,000 patients;

or, in round numbers,

37 deaths in 100 patients

If, now, we proceed by means of the formula referred to, to determine the possible error attaching to this proposition (*i. e.* to the number of facts upon which it is made to rest), we find it to be equal to

$$2\sqrt{\frac{2 . m . n}{\mu^3}} = 2\sqrt{\frac{2 . 52 . 88}{(140)^3}} = 0·11550.$$

This being the possible error in excess and defect, the true influence of the treatment will be comprised between the following limits: —

$$\frac{m}{\mu} + 2\sqrt{\frac{2.m.n}{\mu^3}} = 0·37143 + 0·11550 = 0·48693$$

and

$$\frac{m}{\mu} - 2\sqrt{\frac{2.m.n}{\mu^3}} = 0·37143 - 0·11550 = 0·25593.$$

Thus all that we really learn from this record of experience is, that, under the treatment adopted, the number of deaths may vary between

48,693 and 25,593 in 100,000 patients,

or approximatively between 49 and 26 in 100 patients.

In other words, if we were to employ the same mode of treatment in a great number of cases of typhus fever, we might lose any number between about a fourth and a half of our patients.*

The same formula is equally applicable to the solution of doubtful questions relative to the results of two or more series of facts which we are desirous of comparing. It may happen that the difference between the average result of one series of facts and that of a second series, is so inconsiderable, as to leave us in doubt whether it may not be explained by a reference to the limits of error to which the number of facts in either return is liable.*

It often happens, that the average results of two series of observations relating to two alternative events (such as the events of death or recovery in particular diseases, the birth of a male or female child, &c.) approximate so closely, that we are at a loss whether to attribute the slight difference existing between the two averages to coincidence, or to the operation of certain efficient causes. If the number of observed facts be small, the difference between the averages derived from the two series of facts may be so slight as to fall short of the difference between the limits of error in excess or defect. The same result may also happen with any number of facts, however considerable. In order to solve the doubts which necessarily attach to such close approximations, a mathematical formula has been brought into requisition, and employed in the formation of tables applicable to this purpose. Such a table is subjoined. The mode of applying it will be presently explained.

The use of this table will be understood from the following example: — In the six years 1839–44 there occurred in England, on the average of those years, 515,478 births, of which 264,245 were males, and 251,233 females. As the difference between these two numbers is not very considerable, a question might arise, whether that difference is not compatible with the error in excess to which half a million of facts is liable. The use of the formula on which the foregoing table is founded, would at once clear up this doubt.

264,245 male births in a total of 515,478, is equal to

512,904 male births in 1,000,000 births.

But, on the supposition that the male and female births are really equal in number, we have the limits of variation equal to 500,000 $+\sqrt{\frac{2}{515478}}$ and 500,000$-\sqrt{\frac{2}{515478}}$, or 500,000+000,624 and 500,000—000,624, or a maximum of 500,624, and a minimum of 499,376. The difference by the formula is, therefore, 1248 in the million, while the observed difference between the highest and lowest number of male births occurring in the six years 1839–44, is 514,809—511,781, or 3,028. The inference, therefore, is irresistible, that the excess of male births is due to some efficient cause or causes, and that it is not merely an error to which the number of half a million of facts is inevitably exposed.†

* Gavarret, Principes Généraux de Statistique Médicale, p. 284.

* For illustrations of this application of the foregoing table, and of the formula from which the figures are calculated, see Gavarret's Statistique Médicale, p. 80. et seq., and notes, p. 274.

† Several applications of this table and of the formula from which the figures are derived, will be

Table of the Limits of Variation compatible with an equal Chance relative to two observed Events.*

Provision having been thus made by the two preceding tables for testing the sufficiency of average results based upon different numbers of facts relating to two alternatives, and determining the possible variation or limits of error to which the numbers of facts in question, considered simply as facts, without regard to their peculiar nature, are liable, provision still remains to be made for testing in like manner the value of those averages, which belong especially to the domains of physiology and hygiene, namely, the average number of the pulse and respiration, the average age at death of different classes of the community, &c. In the absence of tables specially adapted to this purpose, it must suffice to state, in general terms, that the averages derived from a given number of facts are not to be regarded as strict expressions of the truth, but as approximations more or less remote, as the number of facts is less or more considerable.

But a very important question here arises: — To what extent, and under what restrictions, do calculations based on mathematical formulæ and derived from abstract reasoning, admit of application to the results of actual observation? Conceding, as we may safely do, the soundness of the formulæ, there is yet great room to doubt the propriety of their application to the average results of observation. For if we suppose a mathematical formula to be applied successively to a long series of averages derived from the same number of facts, it must obviously administer a similar correction to those averages which happen to coincide with the true average, and to those which lie at the two extremes. This consideration is sufficient in itself to condemn the use of mathematical formulæ, except as a means of exhibiting in a striking light the possible error attaching to a small number of facts, considered abstractedly as facts.

From the foregoing considerations, then, it would seem to follow, that although averages derived from small numbers of facts are subject to a considerable amount of possible error, there is always such a probability of their coinciding with, or not differing widely from, the true averages, as to justify their employment as standards of comparison and data for reasoning. At the same time it must be conceded, that averages derived from small numbers of facts stand in need of a confirmation which averages drawn from larger numbers of facts do not require, and that in using the former we are bound to speak with a reserve proportioned to the scantiness of our materials.

Of extreme values derived from observation. — As averages founded upon large numbers of facts are numerical expressions of true probabilities, so extreme values are expressions, in the same precise language, of possibilities. Both orders of facts have their scientific and practical applications; but those applications which belong to the extreme values have been less attended to than those which pertain to averages.

One obvious use of extreme values is to confirm and strengthen the conclusions drawn from averages. Thus, if we wish to ascertain the relative duration of life of two classes of persons, we may make use of the greatest age attained by either class in confirmation of the mean of all the observations; and the coincidence of the one with the other will give increased confidence in the general result.

Another important use of extreme values is as a test of numerical theories. Two apt illustrations of this application of figures are afforded by that practical science which deals most largely in possibilities — Forensic Medicine. M. Orfila, in his "Traité des Exhumations," states that it is possible to determine

found in the work of Gavarret, so often quoted, from p. 143. onwards, and in the notes at p. 286. et seq.

* The formula employed in the construction of this table is

$$0{\cdot}50 \pm \sqrt{\frac{2}{\mu}}$$

where μ, as before, represents the total of the observed facts. The table will be found at greater length at p. 230 of Gavarret's work on Medical Statistics.

approximatively the stature of the skeleton and of the body by measuring one of the cylindrical bones; but instead of testing the value of this conclusion by making use of the extreme values, he contents himself with a rough average. It appears, however, that if we take several cylindrical bones having the same length, and compare them with the corresponding ascertained stature of the skeleton, the extreme statures are very wide apart. Of seven ulnas, for instance, having each the same length (viz. 10 inches, 8 lines), one corresponded to a stature of 6 feet 1¼ inch, and another to a stature of only 5 feet 5 inches. The difference of 8¼ inches shows the possible error which might be committed by trusting to this standard of comparison, and demonstrates its futility.

The other illustration is afforded by the well-known test of the absolute weight of the fœtal lungs. It used to be laid down as a rough average that in still-born mature children the weight of the lungs was one ounce, and in children that were born alive two ounces. More accurate observation showed that this rough guess was very far from the truth. It was only, however, by the aid of extreme values that the utter worthlessness of this test could be proved. It resulted from the collation of a moderate number of observations that the lowest weight before and after respiration were the same to an unit, while the greatest weight of the lungs of still-born children, in two instances, surpassed the greatest weight of the lungs of children born alive. Nothing could more clearly demonstrate the insufficiency and invalidity of this test.

The same general principle which applies to averages applies also to the extremes, namely, that the value of the extremes increases with the number of observations from which they are selected. It is obvious, however, that a larger number of facts will be required to arrive at a true extreme value than to obtain a close approximation to the true mean: 10,000 facts, for instance, may give a true mean duration of life for the inhabitants of any country; but as many millions may not happen to embrace the greatest attainable age.

The same principles, then, apply both to the mean and to the extreme values derived from observation. To obtain a correct mean or a probable extreme, we must multiply our facts.

STATISTICS, VITAL. See Vital Statistics.

STOMACH and INTESTINAL CANAL. See Supplement.

SUBCLAVIAN ARTERIES (*Arteriæ subclaviæ*, Lat.; *Artères sous-clavières*, Fr.; *die Schlüsselbein Pulsadern*, Germ.). — These arteries, two in number, are the great vessels destined to supply the upper extremities with blood. Each passes to the corresponding extremity as a continuous trunk, which in its course gives off numerous collateral branches to the larynx, neck, nervous centres, thorax, &c.

The subclavian arteries on the right and left sides respectively differ from each other in their origin, length, direction, and in their relations to surrounding parts,—differences, however, which occur in the first stage of these vessels only: thus, on the right side, the subclavian artery is derived from the Arteria innominata, and on the left from the arch of the aorta; but on both sides alike the lower or outer margin of the first rib marks the termination of each vessel, which, in its further course towards the upper extremity, is designated by the name of Axillary.

The course of each subclavian artery may, in general terms, be described as representing an arch, the convexity of which looks upwards towards the neck, whilst the concavity has an aspect downwards, and corresponds closely to the apex of the lung. On the right side the extremities of this arch are nearly on the same level, the outer, however, passing a little lower down than the inner; whilst on the left side the reverse obtains, the inner (or cardiac) extremity of the arch of the left subclavian artery, which springs from the aorta, being on a much lower level than the outer. Owing to the difference in the origin of these vessels, the left subclavian artery has a stage within the thorax, which does not belong to the artery of the right side.

The subclavian artery on each side is accompanied by a vein of large size; the direction of the vein is much more transverse than that of the artery, so as to resemble in some respect, as Cruveilhier expresses it, "the cord of the arc which the artery describes:" the subclavian vein is consequently the shorter vessel of the two.

The course of each subclavian artery may be divided into *three stages*, to which the majority of anatomists agree in assigning the following limits:—

A *first stage* comprises that portion of the vessel, from its origin, to the inner, or tracheal edge, of the scalenus anticus muscle.

A *second stage* includes so much of the artery as is contained between the scaleni muscles; and the

Third stage extends from the acromial edge of the scalenus anticus muscle to the lower or outer margin of the first rib: at this latter point the axillary artery commences.

According to some anatomists (as Bichat), the outer margin of the scaleni muscles is the limit between the subclavian and axillary vessels; others (as Cruveilhier) insist upon the clavicle as the line of demarcation between these two great trunks; but the stages above assigned to the subclavian arteries are strictly in accordance with the views of British anatomical authorities.

The *subclavian vein* may be divided into *two stages*, which correspond to the second and third stages of the artery; at the inner edge of the scalenus anticus muscle on each side of the neck, the subclavian joins the internal jugular vein to form the vena innominata (of Meckel), *which latter vein consequently corresponds to the first stage of the subclavian artery.*

As the right and left subclavian arteries differ from each other essentially in their first stage, it is necessary to describe them separately in this portion of their course.

First stage of the right subclavian artery. — This portion of the vessel varies from one to two inches in length; it extends from the summit of the arteria innominata to the tracheal edge of the anterior scalenus muscle, and passes in a direction outwards, and slightly upwards. At its commencement it lies to the right of the trachea, and is concealed by the sterno-clavicular articulation.

In this stage the artery is contained *in the antero-inferior triangle* of the neck. The following structures here constitute its *anterior relations*, and are described in the order in which they present themselves in dissection: — The skin, and subcutaneous cellular stratum, with one sheet of the cervical fascia, being divided, the tendon of the sterno-mastoid muscle (sternal origin) is exposed: behind it is a cellular interval of constant existence, though of variable extent, where anastomosing veins and small arterial twigs ramify. The outer edges of the sterno-hyoid and of the sterno-thyroid muscles are more deeply placed; the latter extends much further outwards than the former, and hence it more directly overhangs and conceals the subclavian artery. These muscles are contained in distinct sheaths (furnished by the deep cervical fascia), which isolate them, as well from the superficial as from the deeper-seated parts: the layer of fascia which forms the back of the sheath of the sterno-thyroid muscle is the deepest lamina of the cervical aponeurosis; towards the middle line it invests the front of the trachea, and the deep thyroid veins; externally, it covers the carotid and subclavian arteries, with their accompanying veins, and is connected to the scalenus anticus muscle, whilst, inferiorly, it is attached to the clavicle, to the sternum, and to the "thoracico-cervical septum," through the intervention of which it is connected with the fibrous layer of the pericardium. On the removal of this fascia from the region under consideration, the *immediate anterior relations* of the subclavian artery are exhibited; they are as follow: —

a. The *right vena innominata*, its satellite vein, lies anterior to the artery in the first stage of its course, but on a lower plane, and separated from it by the phrenic and vagus nerves, and by the internal mammary artery.

b. The *internal jugular vein*, which passes downwards and outwards into the subclavian vein, in order to form with it the right vena innominata, crosses the front of the artery nearly at right angles: an interval (the result of the inclination outwards of the internal jugular vein) occurs between this vein and the common carotid artery; and here

c. The *vagus nerve* passes over the subclavian artery; whilst internal to this point the subclavian artery is enveloped in a *nervous sheath*, formed of

d. The *cardiac filaments* of the sympathetic nerve.*

e. Lastly, the *phrenic nerve* constitutes an important anterior relation of the subclavian artery, passing anterior to the very last portion of the first stage of the vessel, though not in contact with it. The trajet of the nerve is external to that of the internal jugular vein, which, as before mentioned, crosses the same aspect of the artery. There is no actual contact between the phrenic nerve and the subclavian artery, because the nerve, as it leaves the inner margin of the scalenus anticus muscle, lies on and crosses the origin of the mammary artery, which thus separates the nerve in question from the trunk of the subclavian. The relation of

f. The *vertebral vein*, to the subclavian artery, is subject to much variety. According to the descriptions of most anatomists, it passes posterior to the artery; but the writer has found this vein nearly as often in front of the artery as behind it; and occasionally he has seen the vertebral vein terminate in two branches, of which one passed on the anterior, and the other on the posterior aspect of the subclavian artery, so as to encircle that vessel before they opened into the vena innominata. When the vertebral vein is single, and passes over the front of the subclavian artery, it usually lies internal and parallel to the internal jugular vein.

The *anterior relations of the first stage of the right subclavian artery*, are, therefore, the following: —

1. Integument, subcutaneous areolar tissue, fascia.
2. Sterno-mastoid muscle, sterno-clavicular articulation.
3. Sterno-hyoid and thyroid muscles, isolated from one another, and from the last-named muscle, by layers of the cervical fascia.
4. The deep layer of the cervical aponeurosis.
5. The phrenic and vagus nerves, and the cardiac filaments of the sympathetic nerve.
6. The right innominate, and internal jugular veins, and *sometimes*
7. The vertebral vein.

The remaining relations of the artery in its *first stage* are the following: —

Inferiorly, it corresponds to the loop of the

* Vide art. NECK, vol. iii. note to p. 575.

recurrent nerve, *which sometimes has an anterior relation to the artery also,* in consequence of its arising from the pneumogastric at an unusual height in the neck.

Superiorly, it gives off the vertebral artery opposite a triangular interval, between the scalenus anticus and longus colli muscles.

Posteriorly, it corresponds from within outwards, to the transverse process of the seventh cervical vertebra, to the inferior cardiac filaments and inferior cervical ganglion, of the sympathetic nerve, to the recurrent nerve, and finally, to the cone of the pleura.

Nearly *the outer half* of the posterior surface of this portion of the subclavian artery is thus closely related to this serous sac, being usually that part of the vessel which is external to the origin of the vertebral branch, and covered on its anterior surface by the internal jugular vein.

First stage of the left subclavian artery.— The subclavian artery on the left side arises within the thorax, from the termination of the second stage of the arch of the aorta, at the level of the second dorsal vertebra; it thence assumes a direction nearly vertically upwards, to the inner margin of the scalenus anticus muscle, and lies to the left side of, and anterior to, the two upper dorsal vertebræ, from which it is but a short way distant.

Whilst in the cavity of the thorax, the left subclavian artery corresponds, *posteriorly*, to the inferior cervical ganglion, and cord of the sympathetic nerve, to the thoracic duct, and more remotely to the longus colli muscle and spinal column. *Anteriorly*, it is in relation with the pleura, and more immediately with the left pneumogastric and phrenic nerves (the latter descends parallel to the artery, but the former crosses it very obliquely, from above downwards and inwards), with the vertebral vein, the confluence of the internal jugular and left subclavian veins, and the great venous trunk which they form by their confluence, viz. the left vena innominata. *Internal and posterior* to the artery are placed the œsophagus and the left recurrent nerve; *internal and anterior* to it, is the left common carotid artery; whilst *external* to the artery, throughout the entire of its thoracic stage, are the left lung and pleura.

After a course within the thorax of about two inches and a half, the left subclavian artery pierces the "thoracico-cervical septum," inclines outwards and a little forwards, and attains the tracheal edge of the scalenus anticus muscle, when it bends abruptly outwards; this *terminating portion* of the first stage of the vessel (which alone belongs to the cervical region) has, *anterior* to it, the left internal jugular vein, the vagus and phrenic nerves, and the thoracic duct, just before its termination in the great subclavian vein; in addition to these relations, the left subclavian has *the same coverings* as the corresponding portion of the subclavian artery on the right side.

Differences between the right and the left subclavian arteries, in their first stage.—Length. The first stage of the left subclavian artery is much longer than that of the right, which it exceeds by about the length of the Arteria innominata. In the old subject, however, the difference is scarcely so great, for at this period of life, the part of the arch of the aorta, from which the left subclavian artery arises, is higher than that portion of it from which the innominata springs.

Position.—The left subclavian artery is nearer to the spinal column, the right to the clavicle and sternum; consequently the *depth* of the artery from the surface is considerably greater on the left side than on the right, a circumstance which adds greatly to the difficulty of the operation for securing the left subclavian artery in a ligature.

Direction.—On the left side, the artery in its first stage runs almost vertically, but as it approaches the scaleni, it inclines outwards and forwards, in order to pass between these muscles; this latter part of the vessel is situated in the neck, and is the only portion of its first stage found there. On the right side, the subclavian artery runs nearly horizontally outwards, and is placed throughout the whole of its first stage within the limits of the antero-inferior triangle of the neck; for although somewhat concealed at its origin by the sterno-clavicular articulation, yet it may be removed from under cover of that joint, by extending the neck, and depressing forcibly the shoulder and clavicle.

Relations.—a. *Pleura.*—The pleura is an anterior relation of the commencement of the left, but a posterior relation of the termination of the right subclavian artery.

b. *Veins.* —1. *The satellite vein* of the right subclavian artery, in its first stage (the right *vena innominata*), is parallel to the artery, though on a plane anterior and inferior to it, whilst the corresponding vein on the left side crosses the left subclavian at right angles.

2. *The internal jugular vein* runs parallel to the left, but intersects at right angles the front of the right subclavian artery.

3. *The vertebral vein* is usually anterior to the artery of the left, but posterior to the artery of the right side.

c. *Nerves.*—The *phrenic*, *vagi*, and *sympathetic* nerves are necessarily parallel to the left subclavian artery, in the first stage of its course, in consequence of its vertical direction, whilst they run at right angles to the corresponding part of the right, by reason of its transverse course; in other respects, however, these nerves hold the same relative position to the subclavian arteries at either side, the phrenic and vagus being anterior, and the sympathetic posterior, to the right and left subclavians respectively. Lastly, the *recurrent laryngeal* nerve passes behind the right subclavian artery, looping round its under surface, whilst the nerve on the left side encircles the arch of the aorta, internal to the origin of the left subclavian artery; the recurrent is consequently related to the inner side of the left subclavian artery, but at no part of its course does it lie posterior to that vessel.

d. *The thoracic duct and œsophagus* are connected with the artery of the left side, exclusively. *The former* holds a double relation to that vessel; *in the thorax* it passes *behind it*, *in the neck* it rises high above it, and then bends downwards *in front of it*, to open into the confluence of the great veins. *The œsophagus*, as has been mentioned, lies to the right of the artery.

The differences which have thus been pointed out, are of material importance with reference to the operations upon these two arteries.

In the remainder of their course the subclavian arteries are perfectly symmetrical, and one and the same description will apply to both.

Subclavian arteries in their second stage. — In its second stage each subclavian artery lies in a remarkable intermuscular space, bounded by the scaleni muscles. These muscles (scalenus anticus and scalenus posticus) are closely approximated to each other at their attachment to the tubercles of the cervical transverse processes; but in descending to their insertions they diverge, leaving between them a space truly triangular, of which the base, placed inferiorly, corresponds to the first rib, and to a small portion of the second. In this space the subclavian artery, the brachial plexus of nerves, and the cone of the pleura, are situated. *In front*, the artery is in contact with the *anterior wall* of this triangle, constituted by the *scalenus anticus* muscle; *behind*, it is separated from the posterior boundary of the triangle by the summit of the *cone of the pleura*, which ascends thus high into the interval between the scaleni, interposing itself between the scalenus posticus and the subclavian artery. Towards the summit of this "*scalene triangle*" the nervous cords which constitute the brachial plexus are placed along the convexity of the artery, superior and external to it.

A fleshy slip (*Scalenus minimus*, Sœmmering) is often found to pass from the scalenus anticus to the lower, or costal extremity, of the scalenus posticus; in this course it runs *between the roots* of the brachial plexus, and consequently subdivides into two the scalene space. The *lower compartment* contains the subclavian artery, the cone of the pleura, and the inferior portion of the brachial plexus, constituted by the seventh cervical nerve, and the cord resulting from the union of the eighth cervical, with the first dorsal nerve; whilst in the *upper compartment* (corresponding to the apex of the triangle), the fifth and sixth nerves of the plexus are seen to unite into a single trunk.

On the front of the scalenus anticus, and separated by that muscle from the subclavian artery, are found the following parts: — Most inferiorly the subclavian vein, lying on the tendinous insertion of the muscle, and under cover of the clavicle; above the vein the transverse branches of the thyroid axis, viz. the supra-scapular, and the transversalis colli arteries, of which the former is the more inferior, whilst the phrenic nerve descends obliquely inwards towards the tracheal edge of the muscle, and intersects these two transverse arteries by passing behind them.

Superficial to all these important structures is the clavicular origin of the sterno-cleido-mastoid muscle. In size, shape, and direction, this muscle accurately corresponds to the scalenus anticus, which lies deeper than it, and from which it is separated by the parts just now stated, to lie on the front of that muscle.

The separation of the subclavian vein from the subclavian artery in their second stage, "constitutes one of the most remarkable features in its (anatomical) history;" this condition is not, however, constant, for the vein has been found to lie with the artery between the scaleni (Blandin), and, in a few other equally rare instances, the artery has accompanied the vein superficial to both muscles (Manec, Quain). Lastly, the artery has been seen to pass through the anterior scalenus, and hence to lie in part behind and in part in front of that muscle (Quain). It is to be understood that these deviations from the normal arrangement are remarkably infrequent.

The *anterior relations of the subclavian artery in its second stage*, may be arranged in *four orders of parts*: —

1. Skin, platysma, fascia.
2. Sterno-cleido-mastoid muscle (its clavicular origin).
3. Subclavian vein, supra-scapular and transverse cervical arteries, phrenic nerve.
4. Scalenus anticus muscle.

Subclavian artery in its third stage. — After the subclavian artery emerges from beneath the scalenus anticus muscle, it inclines downwards and outwards, and thus completes the arch which its entire course represents. In this stage its position is marked by precise limits, which are always recognisable, even in the living subject. The artery, with the vein and brachial plexus of nerves, which still accompany it, is here contained in the postero-inferior triangle of the neck (*Omo-clavicular space*, Velpeau), the several boundaries of which are constituted by the clavicle, and by the sterno-mastoid and omo-hyoid muscles.

Whilst traversing this region the subclavian artery *lies* at first *on* the scalenus posticus, and then passes on the upper surface of the first rib. *The subclavian vein* lies inferior and internal to the artery, and on a more superficial plane than it, throughout the entire of this portion of its course; it also passes with the artery over the first rib. Two superficial grooves in the adult bone mark the trajet and relative position of these great vessels; a *tubercle*, which gives insertion to the scalenus anticus muscle, separates these grooves from each other (that for the artery is the more posterior of the two); it is constantly present, and serves as a guide to point out with precision the situation of the artery, and so assist the operator to distinguish that vessel from the parts which surround it. Such a guide to the artery is peculiarly valuable, because, in operations upon the larger blood-vessels, the touch often fails to discriminate the proper object, the characteristic pulsation of a large artery being, under such circumstances, often wanting.

In the postero-inferior triangle of the neck the artery is *covered by* the integument, superficial fascia and platysma, descending superficial (*supra-clavicular*) twigs of the cervical plexus, and by the external jugular vein. The situation of this vein in the supra-clavicular space, is subject to much variety; it most frequently runs near to the inner boundary of the triangle and parallel to the outer edge of the sterno-mastoid muscle, but frequently descends in the very centre of the space; in the latter case it much embarrasses the operator in attempting to expose the subclavian artery.

Next in order, a number of conglobate glands, and a plexus of anastomosing veins, principally from the scapular region, come into view; these latter usually communicate with the external jugular, or with the subclavian vein. Areolar tissue which presents a laminated arrangement encloses these glands and superficial vessels, and isolates them from the deeper-seated parts.

These structures being removed, the subclavian artery appears to lie within a *second triangle* of smaller dimensions, bounded *internally* by the scalenus anticus muscle, *externally and superiorly* by the omo-hyoid muscle, and *inferiorly* by the first rib; this bone represents the base of the triangle, and over it the artery is seen to pass. At this depth, two collateral arterial branches of considerable size cross the supra-clavicular space, the one, the transversalis colli, *above*, the other, the suprascapular, *below* the level of this portion of the subclavian artery; the latter is placed under cover of the clavicle, and in contact with the front of the subclavian vein. As the suprascapular artery pursues its course towards the shoulder, it crosses in front of the subclavian artery and of the brachial plexus of nerves. Here likewise the clavicle and the subclavius muscle constitute additional anterior relations of the subclavian artery, now near its termination.

The nervous bundle of the brachial plexus is parallel to the subclavian artery in its third stage, and lies superior and external to the vessel; in its descent the lower division of the plexus overhangs the artery, and one or two of the branches (*anterior thoracic*) cross the anterior surface of the artery, and sometimes even encircle it in a nervous loop.

The *anterior relations of the third stage of the subclavian artery* may therefore be thus arranged:—

1. Integument, superficial cutaneous nerves, platysma, fascia.
2. Areolar tissue in layers, glands, external jugular vein, an intricate plexus of smaller veins.
3. Anterior thoracic branches of the brachial plexus, the subclavian vein, supra-scapular artery, clavicle, and subclavius muscle.

Anomalies in the origin of the subclavian arteries.—1. *The right subclavian artery* sometimes arises separately from the arch of the aorta, in which case there is no arteria innominata; the branches that arise from the arch of the aorta are then four in number, but considerable variety has been observed in the relation which the right subclavian bears to the other three branches; thus,

a. It may occupy the usual position of the innominate artery, being *the first* in order of the branches of the arch of the aorta; its relations within the thorax will then correspond with those assigned to the vessel whose place it comes to occupy.

b. It may be *the second* in numerical order of the branches of the arch, arising after the right carotid artery, behind which it subsequently passes to arrive at its proper position in the neck.

c. It may arise after the two carotids as *the third* branch of the arch; or,

d. It may be *the last* branch of the aorta, and occupy the usual situation of the left subclavian artery. Of the varieties already mentioned, this is the most frequently met with, and, according to the statistics of Professor Quain, it occurs once in every 250 examinations.

e. Sometimes (but much more rarely) this vessel arises *below the arch*, from the thoracic aorta, and its position may be so low, that it will furnish some of the upper intercostal arteries.

The course of the artery, when it thus arises from the left of the arch, is very remarkable; it crosses in front of the spinal column, either behind the œsophagus, or between that tube and the trachea, and necessarily passes across the neck behind all the other branches given off from the arch of the aorta. When thus abnormally situated behind the œsophagus, it has been accidentally wounded by a foreign body which had first transfixed that tube. A remarkable example of this occurrence is mentioned by Mr. Kirby, in the 2d vol. of the Dublin Hospital Reports.

The irregularity in question, of the right subclavian artery, was regarded by Dr. Bayford as the cause of difficult deglutition, in a case which had been accurately observed for many years, and this new disease, as he considered it, he quaintly termed "*Dysphagia lusoria.*" *

In those instances, where the right subclavian artery has been found to deviate thus strangely from its usual course, the inferior laryngeal nerve presented a remarkable change of direction, depending no doubt on the altered course of the artery; in all the instances which were noted, the nerve was given off from the pneumogastric, higher up than usual, and passed directly to the larynx, so as not to be entitled to the name of "recurrent." Dr. Hart, who first directed attention to this fact, has thus clearly explained the connection between the unusual position of the artery and

* Memoirs of the Medical Society of London, vol. ii. 1793.

the altered direction of the nerve: "In the earlier periods of the existence of the fœtus, the rudiment of the head appears as a small projection from the upper and anterior part of the trunk, the neck not being yet developed. The larynx at this time is placed behind the ascending portion of the arch of the aorta; while the brain, as it then exists, is situated so low, as to rest on the thymus gland and front of that vessel. Hence it is that the inferior laryngeal nerves pass back to the larynx, separated by the ascending aorta, the left going through its arch, while the right goes below the arteria innominata.

" As gestation advances, the head becomes more distinct, and the neck begins to be formed after the second month, which, as it lengthens, has the effect of removing the brain upwards to a greater distance, and of drawing out the larynx from the chest, in consequence of which the nerves of the par vagum and their recurrents become elongated, and hence the circuitous route the latter are found to take afterwards, forming loops in which the aorta and right subclavian artery are, as it were, suspended."*

2. *The left subclavian artery* is much less liable to vary in the mode of its origin than the right; the varieties observed are also fewer in number. *a.* The origin of the left subclavian artery is sometimes more approximated than usual to the origin of the left carotid, and in a few instances, *b.* its origin is fused into that of the latter, so that these two vessels arise by a common trunk, which is a *left arteria innominata.*

It has been observed in those instances where the arch of the aorta is reversed, so as to pass from left to right, that the same irregularities affect the transposed branches which then arise from it, as have been stated to occur when the arch holds its more usual position.

Branches of the subclavian arteries.—In the number and arrangement of the branches of the subclavian artery so much variety occurs, that no general description could, perhaps, be given, which would accurately describe their arrangement in any one instance, and hence, in works on anatomy, much discrepancy exists on this subject; the following description agrees with that of the best authorities in this country, and is strictly in accordance with the accurate statistical details of Professor Quain.

In its *first stage* the subclavian artery usually gives origin to the following branches—the *vertebral, internal mammary*, and *thyroid axis;* the last, after a very short course, divides in a radiating manner into the *inferior thyroid*, the *supra-scapular* (transversalis humeri), and the *transverse cervical* (transversalis colli) arteries; besides, in the majority of instances, the *left subclavian artery*, in its first stage, furnishes (in addition to the branches already enumerated) the *superior intercostal artery*, a branch which, on the right side, more frequently arises under cover of the scalenus anticus muscle. All these branches arise nearer to the scaleni muscles, and are consequently more immediately covered by the internal jugular vein on the left side of the neck than on the right.

The position of these branches of the subclavian artery, especially on the right side, is of much interest in a surgical point of view. " The situation in which the branches arise *from any large artery* is an important consideration in its history, because of the influence which their presence has on the result of an operation for the cure of aneurism. And, considering the shortness of the trunk, the size of the offsets, and the manner of their arrangement on the parent vessel, it may be confidently stated that there is no artery in which the influence alluded to is more considerable than in the subclavian."*

The following statistics, derived from the author just quoted, are useful to show the average length of the subclavian artery, from its origin to the point where its first branch arises; in other words, the extent of the artery in its first stage, suitable for the application of a ligature.

In sixty-five bodies examined, this distance measured—

$\frac{1}{2}$ inch and under - - -	in 8
More than $\frac{1}{2}$ inch and not exceeding 1 inch - - - -	„ 33
More than 1 inch and not exceeding $1\frac{1}{2}$ inch - - - -	„ 23
$1\frac{3}{4}$ inch (the extreme length) -	„ 1

Occasionally, the vertebral, or inferior thyroid artery, has been seen to arise *very close* to the arteria innominata.

In the *second stage* the subclavian artery most frequently gives off but a single branch, which soon subdivides into the *cervicalis profunda* and *superior intercostal* arteries. It is less usual for these two arteries to arise *separately;* thus, in 285 examinations, this occurred in the proportion of but 1 to $20\frac{1}{2}$, whereas the former arrangement existed in 266 out of the entire number.

In the majority of instances no branches arise from the subclavian artery *external to the scaleni;* but the *posterior scapular artery* (in general the continued trunk of the transversalis colli) frequently arises from the third stage of the subclavian, and so frequently, indeed, that Cruveilhier regards it, not as a variety, but as the normal arrangement. It is computed by Professor Quain that this occurs in the proportion of 1 in $2\frac{1}{6}$ cases.

I. *Vertebral artery.*—This artery, which is the first and largest, is at the same time one of the most regular of the branches of the subclavian artery, from the upper and posterior

* Dr. Hart, in Edinb. Med. and Surg. Journal, 1826.

* Anatomy of the Arteries of the Human Body, with its Applications to Pathology and Operative Surgery (Plates). By Prof. Quain. Part VI.

aspect of which it usually arises. There is no example on record where this branch arose either between or beneath the scaleni muscles.

From its origin, the vertebral artery assumes a direction upwards, backwards, and slightly outwards to the foramen, in the transverse process of the sixth cervical vertebra; having passed through this, it is transmitted from vertebra to vertebra by the foramina which their transverse processes present, until finally it traverses the foramen magnum, where its cerebral, or cranial, stage commences.

Relations.—From its origin until it enters the transverse process of the sixth cervical vertebra, the vertebral artery is placed in a muscular interspace, between the longus colli and the scalenus anticus muscles, where it is related *in front* to the trunk of the subclavian artery, to its own vein, and to the inferior thyroid artery; the last of these, as it passes transversely inwards, is interposed between the *vertebral vessels* and the *sheath of the carotid artery* (in the sheath, the internal jugular vein exactly corresponds to the anterior surface of the vertebral artery). By its *posterior surface*, the vertebral artery is in relation with the inferior cervical ganglion of the sympathetic nerve.

From the sixth to the second cervical vertebra inclusive, the vertebral artery is lodged in the bony foramina of the transverse processes; in the spaces *between* these, it is enclosed by the pairs of *intertransverse muscles*, being in close contact with the anterior set, whilst from the posterior it is separated regularly by the spinal nerves in their trajet outwards. In this part of its course the artery is slightly tortuous, a provision, no doubt, to guard it against injury in the free and varied motions of this portion of the spine. For a similar reason its tortuosity *increases* remarkably in the subsequent stage.

Having passed through the transverse process of the axis, the vertebral artery inclines outwards and slightly upwards, to reach the foramen in the transverse process of the atlas, a deviation from the former vertical course of the artery which is rendered necessary by the superior breadth of the first vertebra.

Whilst engaged in the curved canal (*not* foramen) of the transverse process of the atlas, the artery bends abruptly backwards and inwards, so that on emerging from this bone it becomes *horizontally* placed on the upper surface of the posterior arch of the atlas. Between the occipital bone and the atlas the artery describes *a curve*, of which the concavity, looking forwards and inwards, embraces the occipito-atlantal articulation, whilst the convexity, directed backwards and outwards, is contained in a *triangular space*, circumscribed in the following manner by the small rotator muscles of the head. The *sides* of this triangle are constituted by the superior and inferior oblique muscles respectively, the *apex* is at the transverse process of the atlas, where both these muscles are attached; whilst the rectus capitis posticus major (placed internally) represents the *base*. Deeply situated in this triangular space, the vertebral artery is *covered* by the splenius and complexus muscles, and rests on the posterior arch of the atlas; the bone presents a groove for the reception of the artery; but the sub-occipital nerve, which frequently forms its ganglion in this situation, is interposed. The space which has just been described is occupied by yellow, granular-looking fatty matter, and the occipital artery winds along its upper boundary, freely anastomosing with the vertebral.

The vertebral artery next passes beneath the lower edge of the posterior occipito-atlantal ligament, then perforates the dura mater, and, taking a direction upwards, forwards, and inwards, enters the cranium through the foramen magnum. The posterior occipito-atlantal ligament, by arching over the groove on the upper surface of the atlas, forms a foramen for the transmission of the artery.

As the vertebral artery advances through the foramen magnum, it passes *between* the first and second tooth-like insertions of the ligamentum dentatum, and then ascends, lying *on the anterior surface* of the first of these processes, by which it is separated from the *spinal accessory nerve*, which latter passes upwards *on the posterior surface* of the ligament; here the *lingual nerve* passes outwards to the anterior condyloid foramen, *above* the level of the artery.

Within the cranium, the vertebral arteries, corresponding at first to the lateral aspects of the upper portion of the medulla oblongata, approximate to each other more and more as they ascend, and ultimately unite at an acute angle, opposite the inferior edge of the pons varolii; in this manner the *basilar trunk* is formed.

Basilar artery (*Artère méso-céphalique*, Chaussier).—This artery, larger than either of the vertebral arteries, is yet much less capacious than the two vessels conjointly which unite to form it; its length corresponds accurately to the longitudinal measurement of the pons varolii; it runs along the median depression of the pons, lodged between that body and the upper surface of the basilar process of the occipital bone, and preserved from pressure by the double concavity of the surfaces between which it is interposed.

At its commencement the basilar artery separates from each other the sixth nerves of the opposite sides; the arachnoid membrane and the dura mater, with the transverse sinus of Haller, are interposed between the artery and the bone, whilst the pia mater alone intervenes between it and the pons. At the antero-superior edge of the pons the basilar artery usually terminates in four branches, two for the cerebrum and two for the cerebellum.

Branches of the vertebral artery. — 1. Branches to the prævertebral muscles, which anastomose with the cervicalis ascendens and superficialis colli arteries.

2. Numerous small branches, which enter the spinal canal through the intervertebral

foramina, and which are conducted by the nerves to the spinal cord, where they join and reinforce the proper spinal arteries.

3. In the space between the atlas and occipital bone, the vertebral artery sends several long branches down the neck, which are concealed by the splenius and complexus muscles. Accompanied by smaller branches of the occipital, these arteries keep up an important anastomosis on the back of the neck with the cervicalis profunda.

4, 5. The proper *spinal arteries.* These are two in number on each side, an *anterior* and a *posterior* branch from each vertebral trunk.

The *posterior spinal arteries* arise lower down than the anterior, and pass downwards and backwards to reach the posterior surface of the medulla oblongata; from this the artery of each side descends parallel to its fellow, to which it is connected by numerous transverse branches. Opposite the second lumbar vertebra, the posterior spinal arteries cease to exist as distinct trunks.

The *anterior spinal arteries* are given off from the vertebral near to its termination; these arteries in descending approximate to each other, and at last unite opposite the lower edge of the medulla oblongata; the single trunk thus formed (*anterior median artery of the spinal cord*) descends tortuously in front of the medulla spinalis, and, passing through the very centre of the fibres of the cauda equina, reaches the lowest portion of the vertebral canal, when it anastomoses with branches of the sacral arteries.

The anterior and posterior spinal arteries are connected in every region of the spine with branches of arteries which enter the spinal canal through the "foramina of conjunction;" these *reinforcing branches*, as they may be termed, of the spinal arteries (derived from the cervicalis ascendens and vertebral in the neck, from the intercostal in the back, and from the lumbar and sacral arteries in the lower portion of the spinal column), cause these arteries which they join to preserve a remarkable uniformity of size throughout their entire course. Both the spinal arteries furnish small branches to the dura mater and to the spinal cord.

Branches of the basilar artery. — 1. *The inferior (or posterior) cerebellar artery.* — This artery seldom arises in precisely the same manner at opposite sides of the same subject. It most frequently springs on one side from the vertebral, and on the other from the basilar trunk. Inclining outwards and backwards, in front of the pyramidal body, the vessel in question passes (according as its origin is from the basilar, or from the vertebral artery) *before or behind* the sixth nerve; it then runs through the filaments going to form the ninth nerve, and between the pneumogastric and spinal accessory division of the eighth pair; it is ultimately distributed *internally* to the inferior vermiform process and sides of the median fissure (a branch or two may be traced into the choroid plexus of the fourth ventricle), and *externally* to the inferior surface and circumference of the cerebellum, where it communicates with the superior artery of the cerebellum.

2. *The superior (or anterior) cerebellar artery.*—This artery arises near the antero-superior edge of the pons varolii; it passes in a curved direction outwards and backwards, around the line of junction of the pons with the crus cerebri. It is at first parallel to the posterior artery of the cerebrum, but separated from it by the third nerve. The fourth nerve in its trajet forwards is strictly parallel to the artery as it runs backwards on the side of the pons varolii; the nerve, however, is contained in a canal between the layers of the tentorium, whilst the artery proceeds beneath that partition, and in contact with the upper surface of the cerebellum.

The *branches* of the superior cerebellar artery are numerous; they are distributed to the upper surface and circumference of the cerebellum, anastomosing with the inferior cerebellar artery, and also to the pons varolii, velum interpositum, superior vermiform process, and valve of Vieussens. One small branch of this artery accompanies and separates the facial and auditory nerves, entering with them into the internal auditory meatus. Lastly, some of its branches pass on the upper surface of the tentorium, and are distributed to the inferior surface of the cerebrum.

3. *Posterior artery of the cerebrum.* — The two posterior arteries of the cerebrum are the terminating branches of the basilar trunk; each artery passes at first forwards, then backwards and outwards, following the course of the great cerebral fissure, and partly encircling the crus cerebri. For a considerable portion of its course the posterior artery of the cerebrum is parallel to the posterior (or inferior) cerebellar artery; the two arteries, however, are separated from one another, at first, by the third nerve (which latter, in its further course, hooks round the posterior artery of the cerebrum), and subsequently by the tentorium. At the point where the posterior artery of the cerebrum changes its direction in order to pass backwards and outwards, it is joined by the "posterior communicating artery," and by this means a communication is established between the internal carotid and basilar arteries.

The posterior artery of the cerebrum is chiefly distributed by long slender branches to the inferior surface of the posterior lobe of the cerebrum, but it furnishes, in addition, the following collateral branches:—1. Numerous small twigs which enter the floor of the third ventricle, through the apertures in the locus perforatus medius, or are distributed to the crura cerebri, corpora albicantia, and tuber cenereum; and 2. a *choroid branch*, which winds round the crus cerebri, enters the cerebral fissure, and is lost in the velum interpositum, corpora quadrigemina, and choroid plexuses.

Varieties occasionally observable in the vertebral arteries. — 1. *Of origin.*—*a.* It has already been mentioned that the vertebral artery may arise from different portions of the first stage of the subclavian artery being sometimes nearer, and sometimes further removed, from the innominata; but, independently of these varieties, the vertebral artery *on the right side* is

b. Sometimes furnished by the common carotid artery. In all the cases where this anomaly has been observed, the right subclavian artery was given off *directly* as a branch of the aorta. Again,

c. The vertebral artery sometimes comes off from the arch of the aorta. This irregularity is as unfrequent on the right, as it is common on the left side. When the *left* vertebral artery springs from the arch of the aorta, it usually arises *between* the left carotid and the left subclavian arteries, though sometimes its origin has been found to the left of all the other branches of the arch.

d. In a few instances, more than one vessel has been found to constitute the origin of the vertebral artery; thus, it may be formed by the union of *two roots*, both arising from the subclavian artery, or one from the subclavian and the other from the aorta. In one example, where it was formed by *three roots*, two of these were derived from the subclavian, and the third from the inferior thyroid artery. These roots of the vertebral artery in some instances united before the artery had become engaged in the vertebral foramina, whilst in others the union took place subsequently.

2. *Of size.*—There is often a considerable difference in the size of the two vertebral arteries, which is stated to be most frequently in favour of that of the left side; thus, in 98 observations made by Mr. Davy, the *left* vertebral artery was the larger in *twenty-six*, and the *right* in *eight* instances only.

3. *Of course and relations.*—The vertebral artery may enter the transverse process of the last cervical vertebra (though the contrary has been asserted), or it may enter one of the foramina higher than that in the transverse process of the sixth, which latter it usually selects. When the artery enters any vertebra higher than the sixth cervical, it always occupies an unusually superficial position in the neck, lying external and parallel to the common carotid artery, for which, consequently, it is liable to be mistaken. (*Vide* CAROTID ARTERY.)

The *vertebral vein* corresponds to the cervical stage only of the artery. Its origin is found in some branches from the deep muscles at the back of the neck, joined by one from the occipital vein, and by another which passes through the posterior condyloid foramen. The vertebral vein traverses the canal in the transverse process of the atlas, and descends through the same foramina by which the artery ascends; whilst here it lies *in front* of the artery, and has the same relations as that vessel. Emerging from the foramen in the sixth vertebra, the vertebral vein (liable to the varieties already specified) opens into the vena innominata close to its junction with the internal jugular.

II. *Internal mammary artery.*—This artery arises (more externally than the vertebral) from the anterior surface of the subclavian, and near to the inner margin of the anterior scalenus muscle. From this origin it runs, first forwards, then downwards and inwards, and enters the thorax, lying between the pleura and the internal layer of intercostal muscles.

Previous to entering the thorax, the internal mammary artery is crossed anteriorly by the vena innominata and by the phrenic nerve: the latter intersects the artery obliquely from above and without, downwards and inwards. In the thorax, however, the nerve attains a position much posterior to the artery.

The mammary artery descends on the back of the anterior parieties of the chest a little external to the junction of the costal cartilages with the sternum, and is covered posteriorly by the pleura at the line of reflexion of that membrane to form the side of the anterior mediastinum. Arrived at the cartilage of the third rib, the artery in its farther descent inclines a little outwards, and becomes separated from the pleura by the fibres of the triangularis sterni; the vessel is now placed between that muscle, which lies behind it, and the internal layer of intercostal muscles and the cartilages of the lower true ribs, which constitute its anterior relations. Opposite the cartilage of the seventh rib the mammary artery terminates by dividing into two branches, an *external* and an *internal*.

Branches of the mammary artery. — 1. *Mediastinal branches*, which are distributed to the thymus gland (*thymic arteries*), and the cellular issue of the anterior mediastinum.

2. A descending muscular branch to the diaphragm (*superior phrenic*), also termed, from its so constantly accompanying the phrenic nerve, the *comes nervi phrenici*. This branch accompanies the nerve in a tortuous manner, between the pleura and the pericardium, to reach the upper surface of the diaphragm, where it anastomoses with the phrenic arteries from the aorta.

3. The *anterior intercostal arteries.*—These are distributed to the six upper intercostal spaces; but their number is greater than that of the spaces for which they are déstined, as two branches are frequently found between adjacent ribs, and this arrangement may even prevail in all of these intercostal spaces.

The anterior intercostal arteries pass outwards in the intervals between the two planes of intercostals, in which muscles some of their branches terminate; others are lost in anastomosing with the intercostal arteries from the aorta, whilst many perforate the muscular fibres, and, arriving on the external surface of the thorax, dip into the pectoral muscles and the mammary gland. In both these latter situations the arteries in question communicate freely with the external thoracic branches of the axillary, thus forming an important connection between the circulation of the interior and that of the exterior of the thorax.

The *terminal branches* of the internal mammary artery are two in number, viz. *internal* terminal branch (*Ramus abdominalis*) and an *external* (*Arteria musculo-phrenica*, Haller).

4. The *internal*, or the abdominal branch, is the smaller of the two, yet in direction it represents the parent trunk. Having communicated with the artery of the opposite side behind the xiphoid cartilage, it escapes from the thorax through a small triangular interval between the fibres of the diaphragm, and then immediately enters the sheath of the rectus abdominis, descending between the muscle and the posterior lamina of the sheath. Having arrived opposite the umbilicus, it becomes distinctly continuous with ascending branches of the internal epigastric artery; it likewise furnishes many branches to the substance of the rectus muscle, and others which, piercing the sheath, are widely distributed to the broad muscles of the abdomen.

5. The *external* terminating branch (or the arteria musculo-phrenica), is larger than the internal, from which it separates nearly at right angles, passing almost transversely outwards in a curved course along the superior line of attachment of the diaphragm to the false ribs. In this course the artery gives off, *a.* numerous *phrenic* branches of large size, which enters the diaphragm all along its costal attachment; and *b. anterior intercostal branches*, which supply the *lower* intercostal spaces in precisely the same manner as those from the mammary trunk supply the *upper*, and which have been already described.

Varieties.— The mammary artery presents but few varieties either of origin or position; in 290 out of 297 examinations, this artery occupied its normal position. In one instance it arose beneath, in six instances external to the scalenus muscle, and in one only of the six was it derived from the axillary artery (Quain).

Much more rarely still does the mammary artery deviate in the opposite direction, i.e. *inwards;* it has, however, been seen to spring from the arch of the aorta, and also from the arteria innominata. Occasionally too it arises in common with the thyroid axis.

Two veins (one on either side of it) accompany each internal mammary artery; they are formed by branches corresponding to those given off by the artery, with the exception (according to Cruveilhier) of the vein accompanying the arteria comes nervi phrenici, which on both sides terminates separately. On the *right side* the mammary veins open into the commencement of the vena cava; on the *left side*, they are connected with the corresponding vena innominata. "The mammary arteries are remarkable for the number of their inosculations, and for the distant parts of the arterial system which they serve to connect: they anastomose with each other, and their inosculations with the thoracic aorta encircle the thorax. On the parieties of this cavity their branches connect the axillary and subclavian arteries; on the diaphragm they form a link in the chain of inosculations between the subclavian artery and abdominal aorta; and in the parieties of the abdomen they form an anastomosis most remarkable for the distance between those vessels which it serves to connect, namely, the arteries of the superior and inferior extremities."*

III. *Thyroid axis.* — This artery springs from the anterior aspect of the subclavian trunk, close to the inner edge of the scalenus anticus muscle, and consequently from the very last portion of the artery in its first stage.

The thyroid axis forms a trunk only a few lines in length, which projects forwards and a little upwards: the phrenic nerve is applied against the outer surface of this artery, and still retains the same relation to it, even where the artery arises more externally than usual, as if in such cases the nerve were drawn outwards by the artery. This arrangement was observed where the thyroid axis arose from the third stage of the subclavian. The thyroid axis usually terminates in three branches:—

1. *Inferior thyroid artery.*—From the thyroid axis, this branch passes a little upwards, and then turns inwards and backwards, describing a curve, of which the concavity looks forwards and downwards, corresponding to the carotid sheath. The artery next descends, but soon afterwards inclines upwards and inwards until it reaches the thyroid body, thus forming a second curve the reverse of the former one, for the concavity of this second curve looks upwards and backwards, and is crossed anteriorly by the recurrent nerve.

The *anterior relations* of this artery are the following:—

It is crossed in its first curve, opposite the sixth cervical vertebra, by the sympathetic nerve, which more frequently on the right than on the left side however, joins the *middle cervical ganglion* in this situation. The internal jugular vein, vagus nerve, and carotid artery, contained in their common sheath, are the next parts which cross the artery; and lastly, the recurrent nerve, sub-hyoid muscles, and thyroid gland, lie in front of it.

The recurrent nerve lies in front of the second curve of the artery.

The inferior thyroid artery is *posteriorly* in relation with the vertebral artery, the longus colli muscle, and the vertebral column; and, *on the left side*, with the œsophagus and thoracic duct.

The thoracic duct very frequently passes up behind the inferior thyroid artery to the level of the sixth cervical vertebra, where, bending downwards and forwards, it arches over that vessel and descends *in front* of it, to terminate in the subclavian vein.

* Harrison's Surgical Anatomy of the Arteries. 4th Edition, p. 141. Dublin.

Branches of the inferior thyroid artery. — *a. Arteria cervicalis ascendens.* — This branch (arising from the upper convexity of the thyroid, where that vessel changes its direction to pass downwards and inwards beneath the carotid sheath) passes upwards on the superficial surface of the scalenus anticus, parallel and internal to the phrenic nerve. The cervicalis ascendens (frequently as large as the thyroid itself) furnishes numerous *muscular branches* to the levator anguli scapulæ, longus colli, rectus capitis anticus major, and to the scaleni muscles, some of which anastomose with branches of the occipital artery; it likewise gives off *spinal* branches, which enter the spinal canal along the cervical nerves, and are distributed to the cord, anastomosing both within and without the canal of the vertebra with the vertebral artery.

By some anatomists the cervicalis ascendens is regarded as a branch of the thyroid axis, from which it not unfrequently arises; in some rare instances it has originated directly from the subclavian artery. Sometimes it is of very large size, and takes the place of the occipital artery or of the cervicalis profunda.

b. The inferior thyroid artery furnishes several *descending branches,* which from their destination may be termed *œsophageal, tracheal,* and *bronchial.*

c. Terminal or *thyroid branches.* — The inferior thyroid artery becomes extremely tortuous as it approaches the thyroid gland; at last it divides into two or three large branches, which enter the gland *by its deep surface,* and which, in the substance and around the margin of the gland, communicate freely with the corresponding artery from the opposite side, and with the superior thyroids of the external carotid.

The reader is now referred to the article Scapular Region, in which the remaining branches of the thyroid axis, viz. the *supra-scapular* and *transverse cervical* arteries, have already been followed to their ultimate distribution; it will be only necessary in this place to describe the *cervical* portions of these two collateral branches.

2. *Supra-scapular artery* (*Arteria transversalis humeri*). — This artery is at first directed downwards, but having reached the shelter of the clavicle, it passes nearly horizontally outwards to the superior costa of the scapula. It crosses over the phrenic nerve, the scalenus anticus muscle, and the subclavian vein; it then runs outwards in contact with the vein, and bound to it by cellular tissue; it next passes across the subclavian artery and brachial plexus of nerves, and finally arrives at the supra-spinal fossa, which it enters by passing over the superior ligament of the scapula.

The supra-scapular artery has, *anterior* to it, the sterno-mastoid muscle, the clavicle, and the omo-hyoid and trapezius muscles. It accurately corresponds to the base of the supra-clavicular space.

3. *Arteria Transversalis Colli.* — This artery is larger than the preceding; from its origin it passes transversely outwards over the scalenus anticus muscle and the phrenic nerve; at the outer edge of this muscle, it inclines backwards and runs through the midst of the branches of the brachial plexus. The artery at this stage crosses the summit of the omo-clavicular triangle, above the level of the subclavian artery. In the space between the sterno-mastoid and the trapezius, the transverse cervical artery gives off a large branch, the *cervicalis superficialis,* which is destined for superficial structures, integuments, platysma, glands, and superficial layer of muscles.

The *cervicalis superficialis* ascends in the posterior superior triangle of the neck, through a chain of conglobate glands, and through the meshes of the cervical plexus of nerves, anastomosing with branches of the occipital and vertebral arteries, and passing finally under cover of the trapezius, to which it distributes numerous twigs, as also to the levator anguli scapulæ and splenius.

After this the continued trunk of the transverse cervical artery is usually called *posterior scapular artery,* which has elsewhere been described.

The *posterior scapular,* and the *cervicalis superficialis* arteries, very frequently arise *separately,* instead of springing by a common trunk from the thyroid axis; in such cases the posterior scapular is usually given off by the subclavian artery external to the scaleni.

IV. *Arteria Cervicalis profunda.* }
V. *Superior Intercostal Artery.* } These arteries (as has been already mentioned) generally arise by a short trunk common to both, from the subclavian in its second stage. An analogy may thus be observed between this trunk and the aortic intercostal arteries; for, like them, it divides into an *anterior* or intercostal branch (the superior intercostal artery), and a *posterior* or muscular branch (the cervicalis profunda). The *cervicalis profunda* passes from its origin backwards and upwards, between the transverse process of the last cervical vertebra and the first rib. When a supernumerary cervical rib exists, the artery then passes between this latter and the first dorsal rib. It thus gains the posterior aspect of the neck, and ascends between the spinous and transverse processes of the vertebræ, separated from the laminæ by the deep layer of muscles, and covered by the great complexus muscle.

In this course the cervicalis profunda anastomoses with the large muscular branches which descend from the occipital and vertebral arteries.

The deep cervical artery sometimes passes backwards at a higher or lower level than that above specified; these deviations must be rare, since none of them existed in 40 subjects examined specially with reference to this subject by Cruveilhier. In the extensive tables collected by Professor Quain, and which have already been frequently alluded to in this article, seventeen instances are given where this artery passed between the first and second rib; in a very few examples, it escaped from the thorax through the second intercostal space, and in some other equally rare cases, it has been seen to penetrate between the sixth and seventh cervical transverse processes.

The *superior intercostal artery* passes downwards in a tortuous manner into the thorax, and gives off branches which run outwards and supply the two or three upper intercostal spaces; the artery of the right, usually passes to one intercostal space lower than that of the left side. The branch to the first intercostal space is in general the smallest.

The trunk of the superior intercostal artery, as it descends, has the following relations:—*in front*, it is covered by the pleura and lung; *internal* to it are placed the first dorsal ganglion of the sympathetic nerve, and the longus colli muscle; whilst *posteriorly*, it corresponds to the first dorsal spinal nerve (in its ascent to join the last cervical), and to the neck of the first rib.

In addition to the branches furnished to the intercostal spaces, and which are two or three in number, the superior intercostal gives off several small branches which enter the spinal canal through its lateral foramina, and also a branch which passes downwards and establishes a communication with the first aortic intercostal artery.

It has been already stated that the superior intercostal and the deep cervical arteries most frequently arise by a common trunk; when they arise separately, the left superior intercostal artery is generally derived from the first stage of the corresponding subclavian artery.

Operative proceedings.—It is not intended in this place to enter into all the details connected with the surgical relations of the subclavian artery, since in the article which treats of the surgical anatomy of the neck will be found clearly described the modes of procedure to be adopted by the surgeon in the operations for the ligature of this artery in different parts of its course; the following few observations, which may be regarded as supplemental to those just alluded to, naturally follow the description which has been given of the subclavian artery in the preceding pages.

First stage. — When the relations of the subclavian artery *on the right side*, internal to the scaleni muscles, are carefully reviewed, the *inner half* of this stage of the vessel will appear to be the most eligible for the application of the ligature, and the object of the operator should be to secure the artery on the cardiac side of its vertebral branch, as in that situation the pleura is comparatively little exposed to injury; the jugular vein should lie to the outside, and the vagus nerve to the inside of the ligature, and any undue disturbance of these parts, especially of the latter, ought to be most sedulously avoided.

The artery was tied, for the *first time* in this situation, by Mr. Colles, in the year 1813. In that instance, as in every subsequent one where the operation has been repeated, the result has proved unfavourable; nevertheless, success has been so nearly attained in some of these cases, that few will be found to agree with Blandin in pronouncing this operation "tout a fait irrationnelle;" nor are we to view with favour the alternative first suggested by Mr. Shaw, and lately revived and recommended to the profession in some recent works on surgery, viz., to remove the arm at the shoulder-joint, and to make pressure on the aneurismal tumour.

In the majority of the cases in which hitherto the subclavian artery has been tied internal to the scaleni, the cause of death was referable to secondary hæmorrhage; the unavoidable proximity of the ligature on the one hand to the heart, on the other to the aneurismal sac, and the small extent of this part of the subclavian artery to which a ligature can be applied, without interfering with the collateral branches, are probably the chief circumstances which determine this fatal accident. If, in the desire to avoid the vertebral, thyroid, and mammary branches, the ligature be applied too close to the mouth of the carotid artery, the current of blood through the latter vessel will then, with almost positive certainty, disturb those sanative processes at the seat of ligature, on which the ultimate success of the operation depends; and hence, doubtless, has originated the proposal to secure *at the same time* both branches of the innominata. The incisions necessary to expose the one, would amply suffice for the ligature of the other; the circulation through the head and upper extremity might afterwards be carried on without material injury, and the formation of a coagulum, *more lengthy* than that afforded by the operations hitherto performed, might lead to a favourable result. This suggestion is due to Dr. Hayden, and is mentioned in his account of the case in which he tied this artery in its first stage, so far back as the year 1835.

The following brief particulars of a case which lately came under the writer's notice, may be adduced as furnishing an additional argument in favour of this proposal. A woman, about 25 years of age, became the subject of an aneurism, situated at the root of the neck, which was regarded as originating from the arteria innominata. The subclavian and carotid arteries were tied at one and the same time, on the principle of Brasdor:—"On the fourteenth day after the operation, the ligature came away from the subclavian artery *without any hæmorrhage*, and every thing promised a favourable result, especially as the *pulsation in the tumour had quite disappeared.* On the sixteenth day, the patient, a woman of violent temper, had a quarrel with the nurse, when she jumped out of bed, seized a pillow and some books, and threw them at her: while making this exertion, hæmorrhage set in from the carotid." A renewal of the hæmorrhage proved fatal. On examination it appeared that "*perfect union had taken place where the ligature had been applied to the sub-*

clavian artery, but a small opening was found in the carotid from which the hæmorrhage had proceeded."

In this instance the innominata was healthy; but, a little to the left of the origin of that vessel, the aneurismal tumour, which was of a pyriform shape, sprung *from the arch of the aorta*, and thence passed upwards into the neck, in front of, and overlapping the arteria innominata. It is an extremely interesting circumstance connected with this case, "that the tumour was filled with a firm coagulum."

This is the only instance, as far as the writer knows, *in which a ligature placed on the subclavian artery, in its first stage, became detached without the supervention of secondary hæmorrhage*. In none of the cases where this artery *alone* was secured did this circumstance occur, much less in any of these instances did "perfect union," the result of adhesive inflammation, follow the application of the ligature.*

Until very recently it was thought that the ligature of the subclavian artery internal to the scaleni was feasible on the right side only, and this opinion of British surgeons originated perhaps in Mr. Colles' statement, that "this operation, difficult on the right, must be deemed impracticable on the left subclavian artery." Dr. Rodgers, of New York, has, however, lately succeeded in securing the left subclavian artery in its first stage. The result of this case does not verify the opinion of Velpeau, that "the operation would be much less dangerous on the left side than on the right," as the patient died of secondary hæmorrhage on the fifteenth day.

British anatomists will be little disposed to agree with Velpeau in such a prediction, and still less will they concur with him in thinking that it would be easier to tie the left subclavian artery than the right; on the contrary, the great depth of the left subclavian trunk from the surface, the short distance to which it rises out of the thorax, and the close connection of the veins and nerves with its anterior surface, must entitle this operation to the distinction of being one of the most difficult, whilst the peculiar and unseen risk of wounding the thoracic duct must ever render it one of the most dangerous, in surgery.

Second stage. — The subclavian artery has been tied between the scaleni muscles in a few instances. This operation was first performed by Dupuytren, in 1819, in a case of traumatic axillary aneurism; the result was successful; yet there is nothing in this operation to recommend it, provided there be the option of tying the artery in the supra-clavicular space. Dupuytren did not (as some have supposed) intend it to *supersede* the latter operation; he advised it in those cases only, where the depth of the vessel in its third stage is unusually great, in consequence of some peculiarity of development, or the unnatural elevation of the clavicle produced by an aneurismal tumour.

The *anatomical objections to this innovation*, which is sanctioned by the authority of Dupuytren, are the following, and they are sufficiently important to justify the conclusion that, where a choice exists, the third stage of the artery should always be selected for the application of a ligature.

1st That in order to expose the subclavian artery in its second stage, the division of two muscles is required, viz., the clavicular portion of the sterno-mastoid, and the scalenus anticus.

2d. That considerable risk of injuring the phrenic nerve is incurred.

3d. That the ligature must be in close proximity to the branches usually furnished by the subclavian artery between the scaleni, viz., the cervicalis profunda, and superior intercostal; and,

4th. That from its close connection with the artery, the cone of the pleura is endangered.

These theoretical objections to the ligature of the subclavian between the scaleni, are not the less deserving of notice because they were *originally* passed over in silence, and they go far to disprove the "*innocuité*" of the operation, an advantage which has been claimed for it by Dupuytren.*

The objections which have just been enumerated, are not however of sufficient weight to forbid a repetition of the operation in any case where insuperable difficulties are encountered in attempting to tie the artery in its third stage; under such circumstances, the surgeon would evince both skill and dexterity by dividing, as far as necessary, the scalenus anticus muscle, and thus accomplishing the object of the operation; and in so doing he would follow the example of the late Mr. Liston, who, in a parallel case, thus succeeded in securing the artery between the scaleni.

Where the *outer edge* of the muscle alone is divided, and where proper caution is used, the safety of the phrenic nerve is not necessarily compromised; but without very great caution in passing the needle, the pleura will suffer injury, as it is placed in close contact with the back of the artery. It should also be borne in mind, that the *phrenic nerve* has in a few instances been seen to pass down beneath the clavicle, lying *on the outer edge* of the scalenus anticus muscle; should such an anomaly occur in a person subjected to Dupuytren's operation, the nerve could scarcely escape from injury. This irregularity in the cervical stage of the phrenic nerve, has usually been seen in connection with a variety of origin of the axis thyroideus, which has been already adverted to.†

* The full details of this interesting case, which occurred in the practice of Dr. Hobart, of Cork, will be found in the forthcoming edition of "Flood's Surgical Anatomy of the Arteries," edited by Dr. Power, one of the lecturers at the Richmond Hospital School, to whom the writer is indebted for the facts already quoted.

* Vide "Leçons Oracles," tom. iv.; and M. Marx account of the operation in the "Répertoire Générale d'Anatomie," No. 2.

† It may be presumed that the phrenic nerve was thus unusually placed in a case which occurred in the practice of Mr. Bransby Cooper, and which he

In its *third stage*, the subclavian artery has very frequently been the subject of operation, and the ligature of the vessel in this situation, in a large number of the cases recorded, has been eminently successful. Mr. Ramsden, of St. Bartholomew's Hospital, in the year 1809, was the first who secured the artery in its third stage, and since then the operation has been successfully repeated by many surgeons, in this as well as in other countries.

Although the subclavian artery, above the clavicle, is covered by no muscular fibres except those of the platysma, yet it always lies at a considerable depth, which varies much in different persons; the statement of Dupuytren will generally be found correct, viz., " that the third part of the course of the subclavian artery is placed more superficially in those who have long, slender necks, with lean and pendant shoulders, but is, on the contrary, deeply hidden in persons who have short, thick necks, and muscular shoulders."*

It is an unfortunate circumstance that the disease for which the operation is usually undertaken, should so constantly be the cause of great difficulty in its performance, for an axillary aneurism of any considerable size cannot fail to elevate the clavicle considerably. This fact is well illustrated in the embarrassments experienced in a case where the subclavian artery was tied by the late Professor Todd, one of the surgeons of the Richmond Hospital, and which are recorded in the third volume of the Dublin Hospital Reports. So great have been the difficulties experienced in the operation, that on one occasion Sir A. Cooper was obliged to abandon the attempt, and on another (already alluded to) Mr. Liston was compelled to tie the artery between the scaleni, finding it impracticable to expose the vessel in its third stage.

(*B. Geo. M'Dowel.*)

thus narrates in his published lectures: "Some years ago I performed this operation (ligature of the subclavian artery in the supra-clavicular space) on a clergyman, in the presence of the late Dr. Babington and Mr. Travers; no difficulty whatever occurred, but immediately after its completion the patient was seized with a constant hacking cough, as if resulting from convulsive motion of the diaphragm. This scarcely ceased night or day until the sixth day after the operation, when he died. No post-mortem examination was permitted; but there can be no doubt, in my mind, that the phrenic nerve had been injured, although it could not possibly have been included in the ligature."—Vide Med. Gazette. Lond. Vol. xlii. p. 94. July, 1848.

SUPRA-RENAL CAPSULES.

(*Die Nebenniere*, Germ. *Capsulæ suprarenales seu atrabilariæ*, Lat. *Capsules suprarenales, atrabilaires*, Fr.) — In the bodies of Vertebrata we find a series of organs, which possess a great outward resemblance to the glands, but distinguish themselves from these by the constant absence of a duct. To this class belong the spleen, the thymus, the thyroid, and the supra-renal capsules. On account of their great richness in blood-vessels, these organs have been named "blood-glands," or "glands of blood-vessels," or "vascular ganglia." At present we are tolerably acquainted with the range of their distribution, and the differences of their form in the animal kingdom; we have, also, some knowledge of their minute structure; but, on the other hand, their physiological import remains just as obscure to the inquirers of the present century as it was to the physicians of ages long gone by.

The *supra-renal capsules, glandulæ supra-renales seu renes succenturiati, seu capsulæ atrabilariæ*, form, in the higher Vertebrata, a double organ, which is constantly placed in the neighbourhood of the kidneys; and from this situation they have received their name. So, also, in the lower Vertebrata they often occupy the same situation; but, not unfrequently, they are broken up into a number of small glandular bodies. In the Invertebrata they are altogether absent.

We shall successively consider, 1. The larger series constituted by the differences of form of supra-renal capsules in the animal kingdom. 2. Their structure. 3. Their development. 4. Their physiological relations.

I. As already mentioned, supra-renal capsules occur only in the Vertebrata. But we cannot attribute them to all of these without exception. In the lowest Amphibia and Fishes, these organs have not yet been indubitably recognised. Among the Mammalia, the supra-renal capsules exhibit everywhere essentially the same structure, in spite of many differences of form, size, and situation.

In *Man* they possess a half-moon shaped, or triangular and flattened form, with an antero-posterior slightly arched surface, and a sharp convex margin. At their bases they are deeply excavated, so that by this part they rest on the upper end of the kidney like a cap. The anterior part of the basis of the supra-renal capsule extends for a considerable distance further forwards on the kidney than the hinder part. The whole organ is included in a covering which consists of closely woven areolar tissue; and inferiorly, it is attached by a looser areolar tissue to the kidney. At the base of the organ is also found a well-marked fissure, from out of which passes the supra-renal vein, according to Krause's statement.* The anterior and posterior surfaces of the supra-renal capsules exhibit an irregularly wrinkled appearance, caused by the numerous furrows of the areolar tissue. The size of the supra-renal capsules amounts in the adult to 1—1½ inches (German) in height, and somewhat less in breadth. The greatest antero-posterior thickness occurs in its lowest part, and amounts from 2½—4 lines. In their middle the supra-renal capsules are considerably thinner, amounting only to 1½—2½ lines. Their absolute weight is estimated by Meckel

* Vide Krause's Handbuch der Anatomie. 2. Auflage, Hannover, 1841. Band 1. S. 668.

to be one drachm: according to Krause * it is from 80—120 grains; according to Huschke† from 80—180 grains. The anatomist last named found that its specific weight in the newly-born infant was 1·0333; but Krause states the supra-renal capsules of the adult to be of the somewhat lower specific gravity of 1·0163.

The two supra-renal capsules of the same individual are generally of different size. Usually the right is of somewhat lesser height, but greater breadth, than the left, which has the contrary diameter the larger.

The so-called *accessory supra-renal capsules* are often found in man. They are small round corpuscles, which, in various numbers, are attached loosely to the inner border of the supra-renal gland, or are sometimes imbedded in an excavation on its surface.

The supra-renal capsules of the *Mammalia* essentially correspond with this description.‡ They are always situated on the upper part of the kidneys; sometimes towards the inner part, sometimes on the upper part of their border, as in man. Sometimes they are not so closely attached to the urinary organs as in man, but are somewhat more removed from them. Thus, for instance, are arranged the supra-renal capsules of the Elephant and Seal. But, in opposition to this constancy of situation of these organs, we find very considerable differences in respect of their size and form.

The supra-renal capsules of *Monkeys* closely approach the shape seen in the human subject; but, not unfrequently, their size seems somewhat more considerable. Among the *Carnivora* they are, in the Dog, of an elongated cylindrical form, sometimes thicker at the margin than in the middle, and of a dense solid texture. So also in the Cat, in whom they are roundish, and somewhat flattened. Amongst *Insectivora* they have in the Mole (*Talpa europæa*) the form of a three-sided pyramid. In the Seal they appear very small, and Cuvier found that their size was, to that of the kidneys, as 1—150. In this latter animal the whole surface of the supra-renal capsules is divided into a multitude of lobules, or acini. Amongst all the Mammalia, these blood-glands are largest in the *Rodentia*, their ratio to the kidneys being as 1 to 4 and 5: this is the case, to wit, in Cœlogenys Paca, and in the Guinea-pig (*Cavia cobaia*). They are roundish, and somewhat flattened, in the Rabbit and the Dipus. The supra-renal capsules of the Mouse, the Rat, and the Myoxus Glis, have a shorter form; while, on the other hand, in Hystrix they become more cylindrical.

* Loc. cit.

† Huschke, Lehre von der Eingeweiden und Sinnesorganen des menschlichen Körpers. Leipzig, 1844, S. 357.

‡ Concerning the differences of form of the supra-renal capsules may be consulted the well-known text-books on comparative anatomy of Cuvier and Meckel; and, especially, Nagel in Müller's Archiv for 1836, S. 365., and Ecker, Die feinere Bau der Nebennieren, Braunschweig, 1846.

Amongst the *Pachydermata* they have, in the Elephant, the form of an elongated cone, and their base is divided into two lobes, and turned backwards. In the Pig, their form is about midway between the cylindrical and the prismatic. Besides this, the supra-renal capsules of this animal possess a considerable size. In the Horse they are flattened and triangular, approaching the human form. Among the *Ruminantia* they are, in the Rein-deer, of an oval form, which approximates to the spherical. They are elongated in the Sheep. In the Ox, their shape in some degree resembles that of the kidney. Here they are almost crescentic, not unlike a horse-shoe, and their upper extremity is three-sided. Finally, the supra-renal capsules of *Cetaceans* are, like those of the Seal, exceedingly small, and broken up into a number of small lobes.

We find a similar correspondence in the class of *Birds*. Their supra-renal capsules are generally small in proportion to the size of the body; sometimes spherical, sometimes oval; and, in general, divided into lobules. They lie at the inner extremity of the anterior part of the kidney, often close to the inferior vena cava; and they are covered by the testicles, or ovaries.

In the *Reptilia* these organs are much less known, since only isolated (and not unfrequently contradictory) observations have been made respecting them. Hitherto they have not been found among the Derotremate, Perennibranchiate, and Cæcilian orders of this class.

The supra-renal capsules of the *Saurians* have been very eagerly examined, and most exactly in the genus *Lacerta*. In these animals Nagel found them along the upper extremity of the vas deferens, in the form of two long, small, lobulated bodies. Nagel's observations have been recently confirmed, and added to, by Ecker. The supra-renal capsules, possessing the form stated by Nagel, have a length of $1\frac{1}{4}$ lines, with a breadth of $1\frac{1}{2}$. They lie closely on the vena renalis revehens, or on the vena cava ascendens, which is constituted by the two efferent renal veins. Since the right supra-renal capsule is usually of somewhat larger size, it is wont to lie on the vena cava itself; while the left organ is placed upon the vena renalis revehens. In the male lizard the supra-renal capsules are placed between the vein and the vas deferens; in the female they are situated between that vessel and the ovary. Numerous blood-vessels convey the blood from it into the corresponding veins. The blind worm (*Anguis fragilis*) also possesses long, small, supra-renal capsules; and so, probably, do the *Crocodilus Lucius* and *Ameiva teguixin*. Nevertheless, both the latter animals are at present insufficiently examined.

The supra-renal capsules of the *Ophidia* exhibit a similar condition, the more exact knowledge of which we especially owe to Retzius. They form two long and small bodies, and in the Python binistatus they attain a length of 8 lines. The supra-renal capsules of serpents are likewise distinctly lobulated, and very vascular. In other respects, too, the arrangement of the vascular system exhibits much that is interesting; but to this we shall hereafter return. They always lie closely on the venæ renales abducentes; and, according to the course taken by the vessels just named, they are sometimes nearer, sometimes farther from, the testicles and ovary.

Batrachia. Formerly many zootomists regarded as supra-renal capsules those peculiar yellow finger-shaped masses of fat, which, in these animals, lie superficially to the kidneys, and possess a connection with the sexual organs, in the periodical increase of which they take a share. Only recently have the true supra-renal capsules been recognised; and to these the fatty bodies just mentioned have not the remotest resemblance. To Rathke *, Retzius †, Gruby ‡, and others, we owe the discovery and description of these organs; the signification of which receives an additional and complete confirmation from minute anatomy, as will be hereafter shown. Here the supra-renal capsules no longer form an organ anatomically defined, but are immediately deposited on the abdominal surface of the substance of the kidneys.

Among the tailless Batrachia, they appear in this situation as a golden-yellow streak, which does not extend the whole length of the kidney, but ceases at a distance of one line from its upper, and of two lines from its lower, end. These supra-renal organs also allow a lobular composition to be very distinctly discerned; and they do not extend along the kidney in a straight line, but usually digress into the arched form. They surround the trunks of the efferent renal veins at their exit from the substance of the kidney; so that they seem to be, as it were, perforated by this vessel. By a more careful investigation one may satisfy one's self that the glands are really imbedded in the coats of these vessels. In the tailed Batrachia, on the other hand, we no longer find the supra-renal capsules in the shape of this connected streak, but broken up on all sides into from twenty to thirty separate and irregular lobules. These are seated, partly in the substance of the kidney at its inner border, partly between the kidney and the inferior cava; while they are also partly deposited on the coats of the latter vessel, and the gland-lobules have the same relation to the efferent renal veins as in the tailless Batrachians.

Finally, amongst all the orders of *Reptilia*, the supra-renal capsules are least recognised in the *Chelonia.* The statements formerly made by Bojanus §, that the supra-renal capsules were two long bodies, situated at the inner margin of the kidneys, and a similar statement of Nagel *, have been lately corrected by Ecker.† According to the last inquirer, the supra-renal capsules of the *Testudo græca* altogether correspond, both as regards form and situation, with the similar organs of the Frog; since they lie on the abdominal surface of the kidney, imbedded in its mass, and extend almost the whole length of this organ.

In *Fishes* the supra-renal capsules again appear; but, as regards their situation, form, and number, they are much more diverse than in the other Vertebrata. The supra-renal organs of the cartilaginous fishes were discovered, a long time ago, by Retzius.‡ For a knowledge of them in the osseous fishes, we are especially indebted to Stannius and Ecker.

In the *osseous* fishes they appear as small, whitish corpuscles, of the size of from a pin's head to a pea. Their form is, in general, roundish or oval; their surface is sometimes smooth, sometimes rugged, and broken up into lobules, as is the case in the Pike. According to the observations of Stannius, they have not unfrequently a kidney-shaped form in the Haddock; and, according to Ecker, they are sometimes triangular in the Salmon.

The number and situation of the supra-renal capsules varies greatly in this group of fishes. The presence of two supra-renal capsules ought to be regarded as the rule. They usually lie symmetrically in both halves of the body, as in the higher animals; they may also occur a-symmetrically, or only in one half of the body, as in the genus Pleuronectes; or they may be behind each other, as in the genus Scomber.

But frequently, the supra-renal capsules are present in great number; in which case their position becomes altogether irregular. Thus one meets with three, four, six, or even more supra-renal organs; and Ecker has observed as many as six in the Salmon. In the Pike, in which only two to three supra-renal capsules are present in the adult animal, the inquirer just mentioned found that, in a young animal of one foot in length, the whole kidney was beset with a great number of very small supra-renal organs. I have myself remarked the same condition, and occurring exactly in the manner described, in two Pikes of the same size: but, on the other hand, in another instance it was absent.

As to the situation of the supra-renal organs in the bony fishes, this also is subject to very great differences. Sometimes these glands lie more on the abdominal, sometimes on the spinal, surface of the kidneys. The former seems more frequently to happen; and in this case they generally project at the hinder end of the kidney, from the anterior margin of the hæmal canal of the inferior

vertebral arch: this occurs in the genera Cyprinus, Tinca, Pleuronectes, Anarrhichas, Scomber. Or they occupy more the middle of the kidney, as in the Salmo Salar. On the other hand, they are found on its abdominal surface in the Eel and Pike. They lie in this situation very anteriorly, occupying, in the Eel, the place where the two crura of the renal mass unite. In the Pike they are yet more advanced forwards, so that they come to lie in the middle point of the length of the body.

Amongst the *cartilaginous* fishes, the supra-renal capsules seem in the Squalidæ to be only present as a single mass. This, in the shape of a small ochre-yellow stripe, occupies the dorsal surface of the kidneys. But in the Rays the supra-renal organs form a curved cylinder, which is constricted at two points, and lies on the ureters; at least Retzius formerly stated this to be its condition. Stannius sometimes found in this genus a similar elongated body behind the kidneys: or, in other instances, four or five small glandular corpuscles were present in its place. And the latter observer found that the supra-renal glands of the Sturgeon* consisted of similar corpuscles in much larger number.

The supra-renal capsules of the cartilaginous fishes have a yellow colour, and are also plainly lobulated.

As has been previously remarked, in the least developed fishes the supra-renal capsules have not been discovered, at least not with any certainty, so that their existence must remain a matter of doubt. In the *Myxinoid* fishes, J. Müller† found behind the gills, and on each side of the cardia, a clustered gland which was devoid of an excretory duct. He interprets it as a supra-renal organ; and regards as analogous to it the white specks with which the trunks of the posterior veins of the body are beset in the Ammocætes.‡ But the minute structure of the glands in question in the Myxinoid fishes, which is also described by Müller, seems rather to contradict the explanation attempted. And Ecker discovered a gland in the Petromyzon between the aorta and the great vein of the body, and partly lying in the coat of the latter: but this also had not the structure of a supra-renal capsule.

II. We next proceed to the *minute structure* of the supra-renal capsules, concerning which Ecker has given a very good and fundamental description, so that we shall here in great degree follow him. In Man and all the Mammalia, they exhibit two kinds of substance, which have been designated by the names of *cortical* and *medullary* substance. The first is clearer than the latter, being in Man of a yellowish-brown colour; while the medullary substance possesses a reddish-brown hue. In many instances, the two kinds of substance are little distinguishable by the naked eye, so that the supra-renal capsules exhibit only a simple mass, such as Cuvier has described that of the Elephant to be. Besides this, the amount of the two layers varies very considerably. The cortical substance is of some solidity; while, on the contrary, the medullary matter is very delicate and flaky. This great delicacy, together with its considerable richness in blood-vessels, makes it very probable, that the medullary substance of the supra-renal capsules is decomposed very quickly after death. And this gives rise to the formation of a cavity, containing a brownish-red fluid, which is not unfrequently found in the interior of the human supra-renal capsules. Formerly this cavity was regarded as normal and occurring during life. The name "capsulæ atrabilariæ" is connected with this notion, since these cavities were described as real by the older anatomists. And although decomposition is regarded as the chief agent in the formation of these cavities, yet pathological conditions seem to be by no means without their influence towards them. Thus Rayer tells us the development of cavities may occur in consequence of rupture of the venous coats, and the effusion of blood in the medullary substance.* Nagel also remarks concerning it, that the supra-renal vein alone, which courses in the centre of the organ, may be instrumental to the production of such a cavity, albeit a small one; so that by injections through this vein the whole medullary mass may frequently be torn up, and converted into a cavity. The covering of the supra-renal capsules consists of areolar tissue. At many points of this covering little processes of areolar tissue pass directly into the interior of the medullary substance, and thus separate it into portions or lobes of different form and size. These masses of areolar tissue are finally lost in fine bundles, which separate the elementary parts of the gland from each other. We shall return to this again.

The further composition of the organ which we are now contemplating is better seen in Man than in any others of the Mammalia.

* Gazette Medicale, 1838, p. 57.

In man the *cortical* substance appears to be composed of an innumerable quantity of completely shut glandular vesicles, which are united into a mass by the ensheathing coats previously mentioned. At the first glance one might easily imagine that they were not gland-vesicles, but tubes which, lying close to each other, take a radiating course from the centre towards the periphery. It is only at either margin of the cortical substance that the individual small roundish vesicles can be verified. By more careful examination, we can assure ourselves (as was first stated by Ecker) that this tubular appearance is only apparent, and that it is caused by the glandular vesicles being arranged in rows, so as to cover each other like the tiles of a roof. In this manner the vesicles of a row, especially when they are filled with dark contents, appear like a tube, with a blind termination at each extremity. The observation just mentioned can be best made if the preparation be treated with a dilute solution of an alkali. It will be thus seen that these vesicles of the supra-renal capsules are surrounded by and constructed of a fine, structureless, transparent membrane, to the thickness of which we are unable to assign any measurement, and which, even by the use of the highest magnifying powers of the microscope, appears as only a simple line. This structureless membrane, which modern observers have shown to be a constituent of all glands with the single exception of the liver, we shall indicate by the name of the "*membrana propria*." It is especially distinguished by the fact, that it is not attacked by the dilute alkalies, as caustic potash, and ammonia, but preserves exactly its original appearance; while the contents of the gland are in general completely dissolved by these agents. The use of these applications cannot be too much recommended in examining the glands, as for instance those of the stomach, intestine, &c.—a fact which has been taught me by repeated experiments. The gland-vesicles of the human supra-renal capsules exhibit considerable differences of size; besides which, their form is wont to vary in some degree. The smaller vesicles are roundish, and have a diameter of 8 to 12-1000ths of a line; the larger of these, which seem elongated, have a length of 18 to 25-1000ths of a line, with a breadth of 10 to 15-1000ths. The smallest of these vesicles occur in the greatest numbers at the limits of the medullary substance; while, on the contrary, the larger and more elongated vesicles generally occupy its middle. The glandular contents, which are surrounded by the vesicles, appear, by a low magnifying power, as a dense pap-like mass, which seems to be white by reflected, and dark by transmitted light, and consist of granules. Nevertheless on the application of a powerful lens four constituents may be distinguished; namely,—(1) very fine molecules, (2) fatty granules, (3) nuclei, and finally, (4) cells in different stages of their development.

(1) The fine elementary granules constitute by far the great mass of the contents. They are dissolved by alkalies, but alcohol and ether do not effect their solution, and they are little dissolved by acetic acid; so that they would thus seem to consist of an albuminous substance, or of a so-called protein-compound. They are immeasurably minute, and in this respect resemble the pulverulent molecules which cause the white colour of the chyle.* Their quantity in the gland-vesicles is so large that they render viscous their fluid contents. It is only on the application of water, that they aggregate themselves into masses or flocculi: previously to this they pervade the viscid fluid with the greatest uniformity. We will select for them the name of pulverulent molecules.

2. The fatty granules are usually met with in considerable quantity, and sometimes they are very numerous. As may readily be imagined, they are of very different diameters, and range gradually from the smallest granules, through larger ones, to small drops of fat. The yellow colour of the cortical substance is due to this constituent.

3. The nuclear structures appear united into a granular mass. They have an average size of 3 to 4-1000ths of a line, a form which is usually roundish and less frequently oval, and they belong to the variety of the so-called "granular" nuclei; *i. e.* to those which are formed of a granular mass, and are not vesicular. The substance of these nuclei is insoluble in dilute acids, but is completely dissolved by the application of potash. Ecker has made the interesting observation, that in the embryo the granular nuclei are no longer to be met with, but that their nuclei are rather vesicles; that is, that they possess a wall, which encloses a more or less fluid mass, in which are contained one or two small punctiform nucleoli. The same condition also obtains in the nuclei of other embryonal tissues.

4. Part of these nuclei are experiencing a transition to cell development, so as to form a constituent of perfect cells. The metamorphosis to the cell-form begins by a part of the finely granular mass arranging itself around a nucleus. Little clusters are thus formed, each of which contains a nucleus. The outer surface of such a mass then becomes hardened, so that the most superficial molecules form a wall or shell, the *cell-membrane;* thus the cluster becomes a cell. So that from the fine pulverulent molecules proceed both the cell and the cell-membrane. In conformity with this statement, a microscopic examination of the expressed contents of the gland-vesicles reveals nuclei, surrounded by irregular flocculi of fine granular substance (*b*, *fig.* 542.), and other nuclei, around which this latter substance has formed itself into a well-defined, round, or oval mass of 6 to 9-1000ths of a line in diameter (*c*, *fig.* 542.). Finally, other masses

* Compare with this the experiments of H. Müller, in Henle und Pfeuffer's Zeitschrift für rationelle Medizin, 1845, iii. S. 299.

may be seen, on which an enclosing membrane plainly exists.

The cell development just described holds good of the supra-renal capsules of all Vertebrata. It is thus of very wide distribution. These cells are designated by the name of globules of circumposition (*umhullungskugeln*). The so-called granule-cells, or inflammatory globules, belong to the same class; as also do the globules of fission which originate from the breaking up of the yolk. And I have also observed that the polyhedral pigment cells of the choroid coat of the eye are formed in the same way. Finally (and of immediate interest in this place), I have found that the cells of many other glands are similarly formed; namely, the cells of the tubular gastric glands, the glands of Lieberkuhn and of the large intestine, the glands of Brunner, and probably also those which occur in the urinary tubules of the kidney. It may also be conjectured that the cells of other glands will be found to originate in the same way.

By a gradual enlargement these cells of the cortical substance are metamorphosed into *gland-vesicles* (*e*, *fig.* 542.); so that while in the large gland-vesicles cells and nuclei occur in numbers, the smaller ones contain only a solitary nucleus. These smallest gland-vesicles are no way distinguishable from the larger cells; they also are cells, and the glandular contents are exactly those of the cell, and the membrana propria is identical with the cell membrane. The contrast between these vesicles and cells — a contrast upon which Ecker has laid particular stress — is of little importance. According to this observer, the membrana propria of the vesicle is unchanged by solution of potash, while, on the contrary, the membrane of the cell is dissolved by it. But by a repetition of the experiment one may be assured that it is only a dilute solution which leaves the membrana propria unaffected, and that by a more concentrated solution it is dissolved just as much as the cell-membrane. The difference is thus only quantitative, and is in exact conformity with the gradually increasing hardness of the membrane.

When fine sections of the *medullary* substance of the human supra-renal capsule are examined with the aid of the microscope, it is seen to be considerably clearer and more transparent than the cortical substance; a circumstance which essentially depends on the fact, that the fatty granules occur more sparingly in the former than in the latter. In Man, and in most of the other Mammalia, it is rendered very distinguishable from the cortical substance by the absence of the gland-vesicles. It is found to consist of a basis of fibrous tissue, which is formed by processes that come off from the sheath of the cortical substance, and in which numerous blood-vessels and nerves take their course. In the mass of areolar tissue the pulverulent molecules above described are also met with; and besides these, nuclei and cells in different stages of development.

Where *accessory* supra-renal capsules occur, they contain, according to Ecker, the same vesicles; of which the larger occupy the outside, and the smaller the inside. But the two kinds of substance are not present; the whole tissue answers to the cortical substance of the real supra-renal capsules, and it has a sometimes clearer, sometimes darker, yellowish appearance.

The structure just described obtains with little modification in all the Mammalia. It is true that, at present, only the Carnivora, Ruminantia, Solipeda, and Pachydermata, have been examined. Nevertheless, according to these observations, it is tolerably allowable to generalise concerning all the orders of Mammalia.

In the Ox, the brown cortical substance is divided by strong bundles of areolar tissue into lobules. The gland-vesicles exhibit nothing extraordinary, but, amongst the different constituents of their contents, the fatty granules are much more sparingly present than in man. Gerlach* found the glandular vesicles very distinct in the Sheep. The structure of the supra-renal capsules of the Goat and Pig is identical with that seen in the Ox.

In the Horse, the gland-vesicles of the cortical substance altogether correspond with those of the human subject. Here also the smaller and more spherical lie on the exterior, while the larger and more oval occupy the interior, and offer the tubular disposition already referred to. But their membrana propria is more delicate than in man. In the young Horse the fatty contents of the gland-vesicles are in very small quantity; while, on the other hand, in older animals, it predominates so considerably that it quite conceals all the other contents, and renders their examination very difficult.

But the medullary substance in the Horse offers a remarkable distinction from that of the other Mammalia: namely, that it, as well as the cortical substance, contains gland-vesicles. These have a variable shape and size; and are round, oval, elongated, or sometimes curved in the shape of a bow. The contents are the same as usual, only it is much poorer in fat than the cortical substance; and, on this account, appears much clearer.

The supra-renal capsules of the Rodentia and Carnivora possess the greatest quantity of fat, and are therefore the most difficult of examination.

Notwithstanding this, the white cortical substance of the Rabbit exhibits the usual arrangement: and, besides this, the medullary mass not unfrequently presents small circumscribed collections of fat.

Among the beasts of prey, the Dog and Cat have been examined, and in these the nuclei of the contents are with difficulty discoverable, owing to the innumerable quantity of the fatty molecules. The nuclei are here also granular in the older, vesicular in the younger

* Handbuch der Gewebelehre des Menschlichen Korpers, Mainz, 1849, 2tn Lieferung.

animals. A portion of fat not unfrequently surrounds the cells of the glandular contents; and in this manner large dark globules originate, which completely obscure the enclosed cell. These may especially be seen in the Cat, where they take a clustered arrangement and occupy the limits of the medullary and cortical substance. The medullary substance is poor in fat. Hitherto the gland-vesicles have not been made out with certainty in this fatty cortical substance, but they are very distinct in the Hedgehog.

It yet remains to us to consider the disposition of the blood-vessels, lymphatics, and nerves in the supra-renal capsules of the Mammalia. For this purpose we shall select those of Man.

Vessels. — In the human subject, each supra-renal capsule is supplied with arterial blood by three trunks:—by an *arteria supra-renalis superior*, which is usually present, and comes off as a branch of the phrenica inferior; an *arteria supra-renalis media*, which is usually *double* on each side, and arises from the aorta; and finally, an *arteria supra-renalis inferior*, which is a branch of the renal artery. The further arrangement of the vascular system has been especially examined by J. Müller *, and Nagel †, whose results have been recently confirmed by Ecker. ‡

The numerous small arterial trunks having arrived at the outer surface of the supra-renal capsules, take a different distribution. One part of them immediately pierce the sheath of the organ, and enter its substance; while another portion of them courses for a considerable distance on the outer surface before becoming lost in the interior.

In the interior of the organ itself these small arterial trunks still take a different course. One of these sets of vessels can only be followed for a very short extent in the cortical substance. After a course of scarcely half a line in length, they break up into a capillary network, with long meshes, which encircle the gland vesicles of the cortical substance. The other arterial trunks, without giving off any branches, plunge at right angles through the cortical mass into the medullary substance. Here they break up into twigs which, by devious paths, return again into the cortical mass, to end also in a network of capillary vessels. Thus the cortical substance possesses a closer capillary network than the medullary mass, a fact which is in conformity with the predominant glandular activity of the former stratum. Nagel, in his Essay, has illustrated this distribution of the arterial vessels by beautiful drawings.

The *veins* begin at the common margin of the cortex and medulla. They alone constitute almost all the vessels of the latter portion, since the smallest branches gradually unite to form larger ones, and these finally join to form the *vena supra-renalis*, which occupies the middle of the supra-renal capsule; and, as was stated above, is proportionally very large. "Were we able," says Nagel, "to exhibit this venous texture isolated from the cellular tissue which receives it, the individual smaller veins opening into the venous trunk on all sides, and at very acute angles, would render it most suitably comparable to a poplar tree."

Usually there is a single *vena supra-renalis* for each supra-renal capsule. The right supra-renal vein passes immediately from the gland into the vena cava ascendens; but the left one forms a longer trunk, which opens into the renal vein. But these statements of Nagel are contradicted by others; for instance, by Krause, according to whom two or three veins generally leave each supra-renal capsule.

As far as observations have hitherto gone, this disposition of the vascular system appears to be tolerably constant for all the Mammalia.

The *lymphatics* of the supra-renal capsules are not yet sufficiently known. According to Arnold, there are superficial and deep ones. In animals slain during the digestive act, Ecker could only find the superficial lymphatics, so that Arnold's statements would seem to be doubtful. The absorbent trunks of the supra-renal capsules unite with those of the kidneys and the internal sexual organs, and they open into the thoracic duct.

The uncommonly rich supply of *nerves* possessed by the supra-renal capsules constitutes a very striking phenomenon, and one which finds no parallel in any cognate organs. In Man, these nerves arise from the cæliac and renal plexuses in the form of numerous and proportionally large trunks. It is chiefly through Ecker that we have become acquainted with the further course of the nerves in the interior of the organ. Larger and smaller branches of nerves perforate the cortical substance, usually contained in the bundles of its areolar tissue, or accompanying its arterial vessels, but giving off no primitive fibres. Only in the medullary substance do the trunks of nerves break up into bundles of fibres. The neighbouring bundles often exchange their nerve-fibres with each other, so that, in this way, they form a dense microscopic nervous tissue. It would seem that, in the human subject, no ganglion corpuscles are present in this sympathetic nerve tissue; but, in the Horse, in whom the supra-renal corpuscles are yet richer in nerves than they are in man, some ganglion corpuscles may be seen on the nervous trunks of the tissue. But one must be especially careful against confounding gland-cells of the organ with these ganglion corpuscles, which they superficially resemble. This rich supply of nerves seems only to pertain to the supra-renal capsules of the Mammalia; in all the other Vertebrata, whose supra-renal capsules, as will be forthwith stated, are very similarly constituted, it is completely wanting. On this account, it becomes exceedingly difficult to state what

* Hildebrandt's Anatomie, herausgegeben von E. H. Weber, 4ter Theil, S. 356.

† Loc. cit.

‡ Loc. cit.

object is fulfilled by this united condition of the nerve fibres.

In *Birds*, the structure of these vascular glands is even more uniform than in the preceding classes. No separation into cortical and medullary substance appears to occur in any bird. A single observation of Meckel's states that in the Cassowary the two kinds of substance are to be distinguished; but this statement is contradicted by the numerous negative observations of Cuvier, Ecker, Bardeleben, and Nagel, on all the animals of this class which they have examined, and hence it requires a confirmation. The supra-renal capsules of birds appear of a darkish or clearer yellow colour, which, by the varying amount of blood they contain, tends more or less towards red. They are also enclosed in a sheath of areolar tissue, and exhibit a basis which consists of fibrous tissue and blood-vessels. In this matrix the gland-vesicles lie imbedded throughout the whole thickness of the organ, and they are devoid of any regular arrangement. They are of roundish, oval, pear-shaped, or irregular form. Their size varies from 44 to 56-1000ths of a line, and in the Falco tinnunculus some of them even attain the size of 22-100ths of a line. Their membrana propria is very delicate. The structure here specified may be best witnessed in the supra-renal capsules of large birds; nevertheless, with some care, we may succeed in recognising the gland-vesicles in the smaller members of the class, as, for instance, in the Pigeon.

The contents of their gland-vesicles closely resemble those of the Mammalia. There are the same fine pulverulent molecules of a protein compound; and fatty granules, which are usually in very large quantity, have a yellowish colour, and give rise to the tint possessed by the whole organ. Not unfrequently larger yellow drops of fat are visible. Besides these, we come upon the granular nuclei previously mentioned, possessing a size of 22 to 31-10,000ths of a line. Some of these nuclei are also enveloped in a fine granular mass, and exhibit a transition to cells in the mode which we witnessed in the Mammalia. Not unfrequently the nuclei are completely buried in fatty granules, through which they are only visible as clear spots. In the golden Eagle Ecker remarked complete cells filled with fatty granules; these were probably caused by the usually finely granular cells becoming gradually filled with fat. In many of the gland-vesicles, on the contrary, the fat is remarkably diminished in its proportion to the finely granular substance; and it has been conjectured by Ecker, and with great probability, that this difference in the amount of fat depends upon the different stages of development of the gland-vesicles. In a very young Pigeon I have found scarcely any fat molecules, a fact which has some connection with this statement.

The minute anatomy of the supra-renal capsules of the *Reptilia* is as yet insufficiently known.

In the supra-renal capsules of Lacerta agilis, Ecker was with some difficulty able to recognise the same condition as that seen in the higher Vertebrata; but the presence of a membrana propria around the gland-vesicles was especially indistinct. He only remarked masses of a darkish substance. These masses consisted of fatty granules of the nuclei already described, and of granulated globules, which contained a nucleus, and possessed a size of 31 to 44-10,000ths of a line.

In the Adder, the obscurity of the contents uncommonly aggravates the difficulty of examining their lobulated supra-renal capsules; but in the fœtal Adder of three inches length, Ecker was able to verify the separate gland-vesicles in the usual manner. Here also nuclei were seen; and, besides these, large pale gland-cells, which could not long resist the action of water. Other cells were completely buried in fatty masses, just as they were seen to be in the carnivorous Mammalia.

The arrangement of the vessels of the supra-renal capsules is peculiar in the Snakes, inasmuch as the greater part of the blood is not brought to the organ by means of arteries, but by veins. In consequence of this, the supra-renal capsules have a kind of portal venous system, such as is possessed by the kidneys of Reptilia and the liver of Vertebrata. The afferent supra-renal veins arise by two branches from the wall of the body, and from the plexus venosus of the vertebral canal; and after a tolerably long and isolated course they reach the supra-renal capsules. On an average, the right supra-renal capsule receives two or three branches; but the left, which is wont to be smaller, only one or two. The arterial blood is brought to the supra-renal capsule by one or two vessels which are branches from the aorta.

Both kinds of vessels ramify in the substance of these organs, so as to form a fine capillary network. The efferent supra-renal veins arise from this network in the form of numerous small trunks. They pass from the right supra-renal capsule immediately into the vena cava posterior; but from that of the left side into the inferior cava, and also into the efferent renal vein.

In his examinations of the Testudo græca, Ecker found certain bodies, which he regards as the supra-renal capsules of the *Chelonian* reptiles. By microscopic examination, they appear as yellow granules which are grouped together in heaps. Each of these is enclosed in a membrana propria, and thus constitutes a gland-vesicle. Their contents are altogether identical with those of the Batrachia, to which we shall next apply ourselves.

In the tailless *Batrachia*, the yellow lobules already described consist of groups of vesicles. Their form varies; sometimes it is round, sometimes oval, sometimes elongated or irregular. The vesicles are always closed, and it is only when they are grouped together that they appear at first sight like blind sacs. Fatty granules constitute the greater part of their contents; but besides these, the fine granular substance is also present. Clear spots may also be seen glimmering from amidst the contents of the gland, and isolation shows these to be cells of 5 to 9-1000ths of a line in diameter, with finely granular contents and a nucleus. The application of water renders this more visible. Part of these cells are devoid of the cell membrane, but others of them exhibit it very distinctly. Besides these, free nuclei are found; these are sometimes vesicular and contain a nucleolus, sometimes they appear to be granulated. The nuclei which are included in cells are always of the latter kind.

From these microscopic characters of their contents exactly corresponding with those of the higher Vertebrata, the import of these organs as supra-renal capsules is placed beyond all doubt.

The same structure obtains in the tailed Batrachians, only the nuclei and cells are larger, while a part of the latter are completely enclosed in fat. Numerous branches of the afferent renal veins break up anew in the supra-renal capsules, in order to provide it with venous blood, a condition which reminds us of that seen in the Snakes.

The minute anatomy of the supra-renal capsules of *Fishes* is very similar. In the Salmon Ecker found them consisting of separate lobules, which are deposited in a loose areolar tissue perforated by vessels, and which, in addition, receive a special covering of this areolar tissue. Each lobule is composed of a number of large gland-vesicles, from 5 to 11-100ths of a line in size, which are surrounded by blood-vessels. Their membrana propria is completely structureless. In their contents we again recognise the pulverulent molecules, separate fatty granules, and vesicular and granular nuclei of 2-1000ths of a line in size. The granular substance is rolled around these nuclei in the manner before described; so that part of them come to notice as spheres without walls, while part are real cells, surrounded by a membrane, and of 7 to 9-100ths of a line in measurement. It is not unfrequent to find two or three nuclei, instead of one, in their interior. We have remarked an exactly similar condition in the supra-renal capsules of the young Pike; there is the same fibrous coat, giving off processes which pass into the interior, and thus isolate the gland-vesicles, but the supra-renal organs are less divided into lobules than in the fish previously contemplated. The contents of the gland-vesicles vary according to their size.

In the supra-renal capsules which are smallest of all, and measure under 9-100ths of a line, there are no gland-vesicles to be seen, but only nuclei: to these we shall immediately return. But in supra-renal capsules which are somewhat larger, the nuclei are partly included in cells.

By a yet further enlargement of these organs, the gland-vesicles also appear: they contain fine molecules, fatty granules, and nuclei. These are vesicular, flat, of circular or irregular form, and vary in size from 22 to 30-10,000ths of a line. Each of these nuclei contains a single or double nucleolus. Not unfrequently forms appear which may be connected with a division of the nucleus, where it appears cut through the middle, or even incompletely broken up into three parts.

Finally, the gland-vesicles also contain cells. By enlarging, these cells experience a gradual transition into new gland-vesicles, which are contained within the larger ones; so that we may distinguish them into mother-vesicles and endogenous daughter-vesicles, just as often happens in other cells, to wit, those of cartilage. The endogenous vesicles occur in the older ones in variable numbers. The smaller gland-cells contain only a single nucleus; others possess two or three of them, which sometimes lie closely packed on each other. Finally, in other cells, three, four, five, and more nuclei occur; and in this manner, by an increase in the number of the enclosed nuclei, and at the same time a continual further extension of the cell membrane, the cells experience a transition into glandular vesicles.

These conditions, which were first observed by Ecker, and which I can completely confirm from an examination of the same animal, will quite permit us to conclude as follows regarding the development of the glandular vesicles. In the smallest gland-vesicles a multiplication of nuclei takes place, most probably from those already present, by the method of fission. This multiplication extends itself to free nuclei, as well as to those which are included in cells. In the latter case, the cell-membrane must be more and more extended by the formation of the nuclei; and in this manner the cells of a gland-vesicle themselves are changed into new endogenous vesicles. By this process, the mother vesicle itself is considerably extended; so that, finally, its membrane comes into contact with the sheath of the supra-renal capsule. Finally, after the membrane of the mother vesicle is destroyed new areolar tissue seems to be developed between the secondary vesicles. In this way the small supra-renal capsules of the Pike experience their growth.

In large old Pikes, the process of multiplication and growth seems no longer to occur. In their supra-renal capsules, the fibrous foundation is more considerable in quantity, so that by its means the gland-vesicles are more separated from each other.

So also in the genus Cyprinus, where a precisely similar structure of the supra-renal capsules may be observed, one lights upon conditions of nuclei in the gland-vesicles which suffice to prove the transition of gland-cells into gland-vesicles. As to the problematical organs of the Myxine and Petromyzon, the glands which Müller discovered in the Myxinoid fishes consist of tufts of small elongated lobules, which are clothed with a kind of cylindrical epithelium.* Concerning the glands in

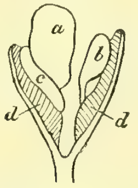
* See the drawing of this glandular structure in J. Müller's Essay.

the Petromyzon, Ecker only remarks, that the microscopic constituents do not afford any foundation for the view that they are supra-renal capsules.

III. *Development.* — The supra-renal capsules begin at a very early date of fœtal life. In the human subject they appear simultaneously with the kidneys in the seventh week. The mode of their commencement is not yet understood with certainty. Nevertheless there is scarcely any doubt that the statement of Arnold, according to which the supra-renal capsules are formed by a projection of the Wolffian bodies, is erroneous. Most embryologists, as Valentin *, Bischoff †, and others, find that another method of beginning obtains, namely, that these organs are developed from an independent blastema, which certainly lies very close to the Wolffian bodies, but has nothing at all to do with them. According to Meckel's observations, both supra-renal capsules constitute at first only a single mass; and Valentin's researches on the embryo of the Dog and Sheep harmonise with this statement. But, nevertheless, this opinion may be founded on an error. Müller found that the supra-renal capsules of a large human fœtus at the eighth week were plainly double, only they lay very closely together at their inferior part. Bischoff's extensive researches on the embryo of Man and other Mammalia, confirm this statement of Müller, and explain the error of Valentin and Meckel. The embryonal form of the supra-renal capsules in man is distinguished from the later condition by its being composed of large lobes; and thus, to a great extent, it resembles its permanent condition in some animals.

It is highly singular that the human supra-renal capsule in the earlier period of fœtal life, is not only much larger in proportion to the size of the body than it is at a later stage, but that it also considerably exceeds the kidney in size (*fig.* 543.). This is shown by

Fig. 543.



From an embryo of 8 *lines in length.*
a, Supra-renal capsule; *b*, Kidney; *c*, Sexual gland; *d*, Wolffian bodies.

numerous observations of Meckel, Müller, and others. In a human embryo of the ninth week, Ecker has recently made the same observation. In the embryo of the tenth to the twelfth week, which measures about two inches in length, the kidneys and supra-renal capsules are for the first time of pretty equal size. While, on the other hand, in the sixth month the kidneys are, as was found by Meckel, already about double the size of the supra-renal capsules, and their weight is to that of these latter as five to two. And as this comparative diminution of the supra-renal capsules proceeds further, the proportions by weight are in the mature embryo as three to one. And even beyond this time, they experience a continual diminution, so that finally, in the adult, the supra-renal capsule is only 1-28th the size of the kidney.

Strange to say, this extraordinary size of these organs during the fœtal period, does not obtain in the other Mammalia. In the earliest period of their embryonal life, the kidneys have always been found considerably larger than the supra-renal capsules. In them both organs appear to grow in precisely equal proportion to each other, so that their (comparative) weight remains the same in the adult animal as in the fœtus. According to Ecker, the supra-renal glands of the new-born kitten are 1-56th to 1-60th the size of the urinary glands. So also the other classes of Vertebrata seem to accord with the Mammalia in this respect. At least Ecker observed, in the embryo and adult animal of the Coluber natrix, the same relative proportion of size between the kidney and supra-renal capsule.

If we regard the situation of the supra-renal capsules in the animal kingdom, we shall find a different condition in the different classes.

It is well known that the Wolffian bodies begin in the embryo at a very early period, and that these, from their structure and function, must be regarded as the kidneys of the embryo; so that the name of "primordial or original kidneys," may be applied to them with all accuracy. Now these primordial kidneys have a very different duration in the different classes of Vertebrata. In Fishes they remain as the urinary glands during the whole of life; since in them, as Baer and Rathke found, an organ similar to the kidneys of the higher Vertebrata is never developed.

The kidneys of Fishes are, therefore, primordial kidneys.

But in the three higher classes of Vertebrata the fact is found to be otherwise. Here the primordial kidneys pertain to only a part of the fœtal life, and then make way for the true kidneys, which are situated beneath the supra-renal capsules.

Therefore, the supra-renal capsules of fishes are placed on the Wolffian bodies, while in the other Vertebrata they are in connection with the kidneys.

In Man, in whom the supra-renal capsules are at first uncommonly large, the primordial kidneys disappear remarkably early, so that in the second month they have vanished even to the smallest relics.

The development of the tissues of these organs is as yet most incompletely known; at present we have only a single statement of Ecker's respecting it. In a human embryo of twelve weeks, this anatomist found a very

* Handbuch der Entwicklungsgeschichte des Menschen, Berlin, 1835.

† Entwicklungsgeschichte der Säugethiere und des Menschen, 1842, S. 291.

distinct cortical and medullary substance. But only part of the morphological constituents were present; viz., the elementary granules, fat, and nuclear structures. Cells, with or without a membrane, were only sparingly found; and gland-vesicles were altogether absent. The embryos of other Mammalia exhibited the same results. In the fœtus of an ox of 1½ feet in length, the vesicles were for the first time detected; and in this instance, as in those of the mature animals previously described, the gland-vesicles were, according to Ecker's opinion, developed from enlarged cells.

In any case it is exceedingly interesting to observe, that in spite of the very early foundation of the supra-renal capsule, this organ seems to rest for a considerable time; since, before their gland-vesicles are developed, we cannot ascribe any activity to the supra-renal capsules. But in man, these vesicles are only developed when the period at which the supra-renal capsules attain their greatest bulk is long passed.

IV. *Physiology.* — Finally we apply ourselves to the functional relations of the supra-renal capsules. Unfortunately, as regards the activity of the glands of blood-vessels, they all veil themselves in an impenetrable obscurity. The recent vast strides of Physiology have passed over them without leaving any traces; the last ten years having only brought some new hypotheses concerning the function of these organs, and very doubtfully enriched the already great number of older conjectures.

It is not the aim of this essay either to answer or to enumerate all that physicians of earlier and later times have imagined as the possible function of the supra-renal capsules. These conjectures, for the most part ephemeral, may be properly left to the history of anatomico-physiological science; and since we willingly disclaim the intention to come forward with a new hypothesis, we will only call attention to some points of this mass of matter.

Now that the minute structure of the supra-renal capsules is known, it becomes even more important to dissent from the opinion of Cuvier. He attributed to the supra-renal capsules pretty much the same function as the kidneys, "because these two organs have much similarity with each other, both in their form, and in the tissues of which they are composed." At present we know how great is the diversity between the tissues of the two organs. Besides, the want of an excretory duct is another fact completely passed over by Cuvier. The opinion of Meckel, that the supra-renal capsules stand in dependance with the sexual functions, rests on just as little foundation, and has been already confuted at length by Nagel in his work. So also the conjecture of Bergmann* and others — according to which the supra-renal capsules stand in a very close relation to the nervous system of the fœtus — is equally erroneous. We will willingly admit the correctness of the observation, that in brainless monsters the supra-renal capsules are generally deficient; but we are forced to add, that we cannot annex any distinct notions to this close relation to the nervous system. Besides, this would suppose that the function of the supra-renal capsule differed in the fœtus and in the adult animal; since certainly no one would seriously defend such a relation of their function in the latter case. And the support which this view seems to receive from the structure of the supra-renal capsules, is likewise only a fallacious one. At one time, attention was drawn to the great richness of the supra-renal capsules in nerves, without reflecting that this is the case in only one out of the four classes of vertebrate animals: and in the same way, the superficial likeness possessed by the gland-cells and ganglion corpuscles was adduced in order to make out the supra-renal capsule as a kind of ganglion. This hypothesis was put aside by the discovery of the gland-vesicles. And especially we would briefly remark, that all those theories which ascribe to the supra-renal capsules a special import during embryonal life, have originated from contemplating them in the human fœtus, in whom they are exceedingly large. Had the supra-renal capsules of other animals been kept in view, those opinions could scarcely have been taken up; and the special size of these organs in the human embryo would have been recognised for that which it really is, an anomalous, isolated condition, which possibly stands in a causal relation with the swift disappearance of the Wolffian bodies. And, as we have already remarked, even apart from this, the absence of the gland-vesicles from the supra-renal capsules of the small embryo is a fact which must not pass unnoticed.

We will, therefore, only attempt to answer such physiological questions concerning the supra-renal capsules which are possibly susceptible of solution, and defer their full understanding to the future.

We will see whether the supra-renal capsules in general can be called glands, and how far they correspond with the other glands of blood-vessels, with the thyroid, thymus, and spleen. And then we may answer the question, "whether the supra-renal capsules generally eliminate a glandular secretion, and whether this secretion is to be regarded as similar or diverse in the whole of the vascular glands?"

Microscopic anatomy has taught us to recognise three kinds of form under which glands are developed in the higher animals. The first is a fine tube or canal of different length; the second is a small globular or elongated sac, which is open at one end; and the third form is that of a globular and completely closed vesicle. A very delicate structureless membrane, the membrana propria, forms the frame-work of all these glands; and it is distinguished by its insolubility in dilute alkalies. On its exterior, it is surrounded by

* Bergmann, Dissertatio de glandulis supra-renalibus, Gottingæ, 1839.

a network of capillaries, while it includes within its interior, glandular contents in very diverse forms. These contents consist, in general, of elementary granules, of an albuminous material, of fatty granules and small drops of fat, and of nuclei and cells in the most variable quantities. Cells, which are the highest development of glandular contents, are not always found: more frequently only nuclei are noticed. It will be recollected that in speaking of the contents of the supra-renal capsules, we have stated that the development of cells occurs by the method of circumposition of a globular membrane, and the same method obtains in a number of the glands.

The first two of the three forms of glands frequently occur isolated, and thus exhibit microscopic glandules of the greatest simplicity; as for instance the stomach glands of Mammalia, the glands of Lieberkuhn, the cutaneous glands of the Frog. In other instances, glandular tubes or sacs are connected to each other in very variable number, and thus form the larger glands. In this way the kidneys and testicles originate from tubes; while from sacculi are formed the multitude of clustered glands, as those of Brunner, the salivary glands, and the pancreas.

The first two forms of glandular structure have no further interest as regards our present object; but the case is very different with respect to the third or vesicular form.

The gland-vesicles have a very diverse size, ranging from microscopic dimensions to a quarter, a half, or even a whole line or more. Their shape is always spherical, so that their membrana propria encloses a globular cavity, which contains, suspended in a fluid, all the different constituents of gland-contents previously spoken of. In very numerous experiments I have never found vesicles of this kind further divided by ensheathing membranes.

Generally the united gland-vesicles are inlaid in the fibrous tissue of the particular mucous membrane of the body; they are sometimes in greater, sometimes in smaller quantity, so that great differences, both individual and generic, may be noticed in this respect. In many places they occur with greater frequency, so as to constitute the rule, and have therefore received a special name. For instance, the glandulæ solitariæ of the intestine, and the lenticular glands of the mucous membrane of the stomach, belong to this category; while in other cases more than one or even many vesicles of this kind are grouped together to form a glandular body of some extent. Amongst such aggregations may here be enumerated the Peyerian vesicles, which form a single layer of this kind in the mucous membrane of the intestine. We find the same grouping in the ovary, where these vesicles are called "Graafian," in honour of their discoverer. But here they are somewhat more widely separated from each other by the thickness of a solid fibrous basis, or by the so-called stroma; and they enclose, beside the usual glandular contents, a peculiar body, the primitive egg or ovum.

The physiological relations of the gland-vesicles, and especially their duration and origin, are as yet little known. The facts may probably be stated as follows. The gland-vesicles arise from cells which enlarge, so that the cell-membrane becomes the wall of the vesicle, and its contents form those of the vesicle also. At least I have observed exactly this occurrence to take place in formation of vesicles in a fish of very low development which inhabits our brook (Ammocœtes branchialis). In this fish a number of glands of this kind may be found at the dilated part of the intestinal canal, on both sides of it near the spiral fold: these remain tolerably small, although they experience considerable variations of diameter. They are densely filled with large, pale, smooth nuclei, of oval or roundish form, the number of which is greater or smaller according to the size of the vesicle. Beside these are seen in the tissue of the wall of the intestine separate cells, which enclose two nuclei in no way distinguishable from those of the gland-vesicles. From these cells they pass, by all intermediate gradations, to the large vesicles. If one may generalise on this observation, it may be stated therefrom, in accordance with the proposition mentioned above, that the shut gland-vesicles proceed from cells. The gland-vesicles in the mucous membranes of the Mammalia are very unfavourable objects for examination; so that, unfortunately, in spite of many attempts, I have not been so lucky as to observe their development. So also I am unable to state in what way the multiplication of nuclei takes place, whether by a fission of the nuclei already present, or whether new nuclei arise independently of the old ones in the fluid of the gland. But I conjecture that the latter is the case.

By their further increase of size, the gland-vesicles come to lie more on the surface of the substance in which they are imbedded. But the membrana propria does not possess an unlimited extensibility, so that a period arrives when it can no longer withstand the contents, and is burst by them. This rending occurs at the place of least resistance, namely, at the upper and most external part, and engages not only the membrana propria of the gland-vesicle, but also the thin layer of fibrous tissue present superficially to this. By the occurrence of this so-called dehiscence of the gland-vesicles, its fluid contents become effused amongst the other constituents. This process has long been known to occur in the Graafian follicle of the ovary; but it may also be seen with the greatest distinctness in the vesicles of the mucous membranes, as well in the separate as in the Peyerian glands. The burst gland-vesicle is thus brought into connection with the outer world, and now resembles a wide-bellied and short-necked flask: it has thus suddenly become converted into a small sac, such as we have already found as a constituent of the glands treated of as belonging to the second variety.

After their dehiscence, the gland-vesicles appear to behave differently. Part of them by bursting arrive at the end of their career. They do not become distended with secretion a second time, but the gland-vesicles cease to exist as such in consequence of further metamorphosis. The ovary, the vesicles of which disappear by the formation of a corpus luteum, affords a proof of the occurrence of this process. While, on the contrary, other gland-vesicles seem to close again, and to become distended with new secretion, in order to their going through the process for a second or perhaps a third time. It is exceedingly difficult to come at the truth respecting this matter, but an examination of the Peyerian glands may afford us some help in the investigation.

Each Peyerian patch consists of but a single layer of gland-vesicles, which in the adult appear all to be at pretty much the same stage of development. No second row of undeveloped vesicles is ever found beneath this layer, such as might be supposed to serve as a compensation for those which have burst; so that a Peyerian patch of glands, after all the vesicles had burst, would necessarily disappear, if no closure of the vesicles followed, unless indeed a power existed to develop a new group of vesicles at some other point. Now although the Peyerian glands of Man and Mammalia certainly show individual varieties in number and extent, yet these appear too small to prove a destruction of the Peyerian vesicles after the manner of the Graafian follicles of the ovary. Besides this, I have never been able to remark the least appearance which could lead me to imagine a new development of the glandular patches. Moreover, it is a well ascertained fact, that in many Mammalia certain Peyerian gland-patches show a constant position and size at all periods. To this category belongs a very large Peyerian patch which exists in the rabbit at the point where the ileum opens into the large intestine. Such structures will scarce admit of any other conclusion than that the gland-vesicles reclose themselves after their dehiscence.

From these observations, which in part depend on researches not yet published, we shall be able to come to a decision respecting the glandular nature of the supra-renal capsules.

In them the same gland-cells appear; the same membrana propria, capable of withstanding alkalies. Exteriorly this is surrounded by capillaries, and interiorly it contains the same mass, consisting of molecules of a protein substance, fatty granules, nuclei, and cells developed by circumposition of a membrane. We also find a development of gland-vesicles from cells identical with that which was met with in the Ammocœtes. The multiplication of the nuclei here occurs by the method of fission. And since, in the supra-renal capsules, these undeveloped gland-vesicles occur in predominant quantity, we may, therefore, well imagine that the old gland-vesicles are destroyed in these organs, in which they undergo dehiscence. But their contents are not extruded outwardly, as are those of the gland-vesicles previously described, but into the fibrous framework of the organ, in which they exist in the fluid form, and from which they are subsequently received into the vascular system either by immediate or mediate resorption.

We are therefore correct in regarding the supra-renal capsules as glandular organs, and their function as secretory; and any hypothesis which ascribes to them a function other than secretory, may be safely considered erroneous.

If we now address ourselves to a comparison of the structure of the supra-renal capsules with that of other vascular glands, we shall see how great a resemblance obtains.

Unfortunately, we do not possess such experimental researches regarding all of them as those which Ecker has published in his work on the supra-renal capsules. Only the thymus gland has found an accurate observer in Simon.* Nevertheless, we already know thus much, that in two of the three other vascular glands, viz., in the thymus and thyroid glands, a similar structure obtains. Bardeleben † was the first to observe what Ecker ‡, Gerlach §, Schaffner ‖, and others confirmed, that in the thyroid gland gland-vesicles occur grouped in masses, imbedded in a loose cellular tissue, and surrounded by blood-vessels. In Man, they are seen with some difficulty; but are more easily made out in most of the Mammalia, and best in Birds and Reptilia. These vesicles, which attain a size varying from 6-1000ths to 5-100ths of a line, begin as cells which measure 5 to 10-1000ths of a line, and which are connected with them by all the transitional forms. Suspended in a fluid which occupies their interior, are varying numbers of elementary granules of an albuminous material; and besides these, fatty granules, nuclei of 2 to 3000ths of a line, and finally, cells with one or more nuclei. In the earlier periods of fœtal life the vesicles are not to be met with; but their place is entirely occupied by cells, — a condition exactly similar to that which was met with in examining the supra-renal capsules.

So also the gland-vesicles of the thyroid appear after some time to be destroyed, and their contents resorbed. This is shown by the fact, that frequently only younger and undeveloped forms of these are to be met with in the adult animal; while in other instances, the fully developed vesicles occur in excessive numbers. Some distinction between the thyroid and supra-renal capsules, although not an important one, may possibly be deduced from the fact, that in most of the Mammalia, the nuclei and cells are ranged as an epithelial stratum on the inner surface of the vesicles, so that the remainder of their cavity

‡ Loc. cit.

§ Loc. cit.

‖ Henle und Pfeuffer's Zeitschrift für rationelle Medizin, 1849.

is filled with a more or less clear fluid. Nevertheless, in Man, the gland-vesicles are generally completely filled with the morphological constituents of their contents.

As regards the thymus, we have lately had Simon's researches extended by Ecker, Gerlach, and Schaffner. The gland-vesicles here likewise enclose similar contents. The quantity of the elementary granules seems to be very variable, and nuclei form the greater part of the contents. In general, cells occur but very sparingly. According to Simon, their number is increased by involution of the organ, in which case, also, fat molecules are wont to appear in place of the elementary granules. As to the gland-vesicles, they deviate from those of the vascular glands hitherto described. In the embryo of the Adder and of Birds, Ecker saw many completely shut gland-vesicles, which everywhere passed into sacculi by pouchings of their membrana propria. In the human thymus, and that of Mammalia generally, only a few vesicles of this kind were found, and the tunics of these exhibited the same condition. Thus the thymus gland exhibits a similarity with the clustered glands; but is distinguished from these by the want of an excretory duct. And these differences of the gland-vesicles, together with the great number of the nuclear structures, somewhat distinguish the thymus from the supra-renal and thyroid glands.

The structure of the spleen is even more different, — if it be allowable to decide upon this organ, which is so uncommonly difficult of examination, from a few observations of a somewhat contradictory tendency. It is only the well-known Malpighian corpuscles which can be regarded as glandular structures. In fact, this opinion would seem to be correct, since Ecker found a delicate membrane enclosing the vesicles. Nevertheless, lately, an opinion has been put forth on many sides, and based on continuous research, that the Malpighian corpuscles are not closed vesicles, but stand in connection with the lymphatics, so as to constitute only vesicular dilatations of these vessels. This view, which is maintained by Gerlach and Schaffner, is especially corroborated by the fact, that the contents of the splenic vesicles differ from those of the other vascular glands, and closely approximate to those of the lymphatic vessels. Thus we remark in their contents, cell nuclei in very predominant quantity, the diameter of which amounts to 2-1000ths of a line. These nuclei appear sometimes smooth, sometimes granular; they often exhibit one or two nucleoli, while in other instances they have none. Roundish cells of 4 to 5-1000ths of a line, and closely surrounding a nucleus, may also be remarked in sparing quantities. The above-mentioned relation of the Malpighian corpuscles to the lymphatic vessels is probably supported by another circumstance. Another cell formation may be found in almost every spleen, and certainly in the splenic vesicles also. They are large, globular cells, measuring from 5 to 10-1000ths of a line, and with contents of a very different kind; so that from this fact one might conjecture that they form a number of very different structures, which, however, are connected with each other by transitional forms. Thus a part of these cells contain more or less dark elementary granules; another part enclose larger yellowish, or yellowish brown and tuberculated corpuscles; while finally, other cells contain, with the latter corpuscles, one or many completely developed blood corpuscles. This group of cells is susceptible of a double interpretation. In the first place, effused blood corpuscles may be enclosed by a cell membrane, and may be broken up into elementary granules in its interior. This view has been taken by Kölliker*, and is supported by pathological appearances. But the process may be exactly the reverse; the blood corpuscles may be developed in the interior of the cells, and then, after the bursting of the cell wall, become free. And should this latter view, which is especially maintained by Gerlach†, ultimately turn out to be correct, then we shall have in the Malpighian vesicles of the spleen a new development of blood corpuscles, just such as occurs after another scheme, in the other district of the lymph and chyle system. So that the spleen would be an organ especially serving for the development of blood corpuscles, and the old explanation set forth by Hewson would be the correct one. But if the process be that which Kölliker supposes, the spleen will exercise the function of destroying the blood corpuscles. In any case, it is worthy of notice, that no such cells containing blood corpuscles occur in the other vascular glands. Gerlach could not discover them in the thymus gland, and they would scarcely have escaped Ecker's careful observations of the supra-renal capsules. So likewise, in a number of examinations of supra-renal capsules, it is impossible to find the least trace of their presence. Therefore by all this the spleen is greatly distinguished from the other vascular glands. Such great differences of structure and contents will not allow us to attribute a like function and a like secretion to all these organs. Certainly we cannot at all state of what kind these differences of secretion are, since the materials prepared by these vascular glands are, as far as regards their composition, completely neglected: but that such differences must exist, I think microscopic research will quite warrant us in saying. In this respect the thyroid gland and supra-renal capsule agree most nearly together, since in general terms, there is a great correspondence in their structure. And, as the spleen is the widest separated from them, so it is not unlikely that future research may remove it from amongst the vascular glands.

Since the chemical constitution of the secretion is unknown to us, we are unable to

* Vide Landis's Dissertation, apparently under Kölliker's direction, Beitrage zur Lehre über die Verrichtungen der Milz, Zürich, 1847. See also the article SPLEEN.

† Loc. cit.

state either the object of the vascular glands in general, or that of the supra-renal capsules in particular. Pathological study also has, up to the present time, failed to afford anything which would allow any safe conclusion to be drawn concerning the function of the supra-renal capsules. By their concealed situation, they elude the experiments of the physiologist; besides this, they are so small, that their secretion can scarcely have any very sudden and visible influence on the vegetative life of the body. So that even by such an eager operative interference as the extirpation of this gland, the wished-for result might scarcely be obtained.

I therefore repeat, that at present we are completely in the dark as to the function of the supra-renal capsules; we know not at all in what way they operate, and on this account all references of the supra-renal capsules to this or that organ — such as have so often been made — are altogether empty and worthless. We may see at a glance that it would be just as correct to assign a relation of the supra-renal capsules to the eye or ear, as to the sexual or urinary organs.

Ecker, who, in opposition to our view, regards the secretion of all the vascular glands as one and the same, keeps its contents of fat and protein compound especially in view, and conjectures that all the vascular glands are adapted to the formation from the blood of a secretion which is rich in protein and fat, and which being subsequently retaken into the current of the blood, in this manner benefits nutrition. But apart from the fact, that one cannot see why such a fluid should take this round-about way through the vascular glands; apart from this, the quantity of protein compounds in the secretion of all the vascular glands of the body, even if we take this at the highest estimate, is far too small to render any enrichment of albuminous materials which the body could obtain in this way other than a very inconsiderable one. The want of an excretory duct affords certainly this information, that the secretion prepared by the vesicles of the vascular glands is again received into the blood; but even this notion has connected with it much that is obscure and uncertain.

The difference of the function of the vascular glands is yet further upheld by the circumstance that their vital duration and activity is different. The function of the thymus is the first to wane; that of the supra-renal capsules seems likewise much diminished in more advanced age; while, on the contrary, the activity of the spleen endures for the whole life. These organs experience an excessive deposit of fat in their vesicles, and by this means gradually disappear.

(*Heinrich Frey.*)*

SWEAT. — The cutaneous secretion is formed by the spiral sudoriferous canals discovered by Breschet and Purkinge. In considering this subject it is important to make the distinction between sweat and that exhalation which is constantly, and at the same time insensibly, excreting from the healthy skin. The latter is the manifestation of a function indispensably necessary for the continuance of life; while sweat may be regarded merely as an occasional result, and as producing on the surface certain excretive products which under ordinary conditions only appear in small proportion on the skin, and find their more natural exit from the organism through other channels. It is true that sweat contains among its constituents the ordinary products of the insensible perspiration, but it also contains other matters of a solid kind which do not appear in a fluid form unless cutaneous excitement be brought about, and which in cold weather and in the case of indolent, inactive persons, adhere to the cuticle, and are gradually rubbed or washed off. These solid matters are not volatile at the ordinary temperature of the skin, and therefore will not pass off from the body in material quantity by any amount of perspiration. They become constituents of sweat, however, inasmuch as they dissolve in the water which, under exercise or owing to excessive temperature, appears on the surface. Thus sweat is constituted of the ordinary aqueous products of the natural perspiration, which appearing in large quantity ceases to be vaporised, and in addition it contains those cutaneous secretions which the water dissolves, but which, when an animal does not sweat, appear in less quantity, and adhere undissolved to the surface. As the ordinary cutaneous transpiration forms an important part of sweat, I shall proceed to consider it before entering on the more immediate subject of the present article.

In the healthy human subject, a portion of water is constantly finding its way to the surface, and under ordinary conditions is vaporised nearly as fast as it is secreted. Some difference is observed in individuals in this respect, however, so that we observe some whose skins are constantly moist, while others, though in perfect health, have the skin almost always dry, yet doubtless performing its ordinary function. Perhaps the most agreeable proportion of perspiration, and that which we should regard as approaching more nearly to the normal quantity, is that which maintains a certain moisture on the surface sufficient to impart an agreeable softness to the touch, and scarcely to convey the idea of moisture. Many attempts have been made to determine the quantity of the cutaneous transpiration, and perhaps nothing has ever been attempted so unpromising in result. It is almost certain, indeed, that we do not transpire equally during any two minutes of the day, and on no two days alike.

Sanctorius, the Venetian physician, whose aphorisms contain much valuable matter, too much neglected by the physiologists of the present day, made lengthened experiments on perspiration. The insensible perspiration has,

* The Editor begs to make his acknowledgments to his friend Dr. Brinton for this translation from the German MS. of Professor Frey.

indeed, been termed "Sanctorian" in honour of him.

This subject, curiously enough, received some attention from the merry monarch Charles the Second, who instituted many experiments on the subject. Among other less exalted, but probably more trustworthy observers, may be mentioned Dodart, Keil, Robinson, Home, and Linings, and of later date Lavoisier and Seguin. According to an experiment of Home, the perspiration during the twelve hours of night varies from 12 to 18 oz., and in $23\frac{1}{2}$ hours the discharge amounted to 3 lbs. $3\frac{1}{2}$ oz. On another occasion, however, the amount was only 2 lbs. $6\frac{1}{2}$ oz. Keil states the medium quantity of perspiration to be 31 oz. only. Robinson states the amount for summer to be 27 oz., and in winter 30 oz. daily. Hartmann, in Germany, makes the daily amount of perspiration 45 to 46 oz. Dodart, in France, gives 40 oz. 3 dr. 26 gr. for summer, and 26 oz. 46 gr. for winter. Sanctorius found that in the warm humid air of Venice, having taken 8 lbs. of ingesta, the perspiration in the 24 hours amounted to 5 lbs., the fæces to 4 oz., and the urine to 69 oz.

The observations made by Linings, in the climate of South Carolina, bear importantly on this subject. He found that while perspiration, as might be expected, was most abundant in the warm weather of summer, the urine diminished proportionally, and that the converse pertained for the winter. He observed the perspiration to exceed the urine during seven months, and the urine the perspiration during five months of the twelve. The largest proportion of urine observed was 143 oz., which occurred in December. The largest proportion of perspiration was 130 oz., and was observed in September. The ingesta were to the perspiration as 2·18 to 1. The perspiration of the whole year was to the urine as 1 to 1·08. These experiments differ from those of Sanctorius and Rye, in showing that the urine exceeds the perspiration even in a hot climate.

On reviewing all that has been done by various experimenters, it appears doubtful whether, even in warm climates, the cutaneous exhalation exceeds that of the urine, and we ought most probably to regard it as considerably below the quantity stated by Sanctorius. It must be remembered that, as in the experiments described above, the perspiration is estimated from the loss sustained by the body during a given period, after subtracting the weight of fæces and urine discharged; we have the pulmonary exhalation therefore included in the account, as well as the cutaneous.

Mr. Cruikshank made experiments which are free from this source of error. He placed his hand in a glass jar, making it air-tight by means of bladder fixed round his wrist and also bound tight to the mouth of the jar. He assumed that his hand presented a surface $\frac{1}{60}$th that of the whole surface of the body, and from that datum arrived at the conclusion that the exhalation from the skin was 7 lbs. 6 oz. in the 24 hours, which, under exercise, would amount to 12 lbs.

Mr. Abernethy made an experiment very similar to the above, but according to his calculation, the exhalation for 24 hours would amount only to $2\frac{1}{2}$ lbs. This extraordinary difference may perhaps be accounted for by the fact that Mr. Abernethy continued his experiment six hours, and Mr. Cruikshank only one hour, and such being the case, the exhalation may have nearly ceased some length of time before six hours had elapsed, owing to the extremely moist atmosphere in which Mr. A.'s hand was placed. Cruikshank, it will be seen, would have to multiply by 24, and Abernethy by 4 only for the result of 24 hours. Thus the former would magnify the excess (obtained by the first hour affording a dryer atmosphere) into an important quantity.

Lavoisier and Seguin have made excellent experiments with a view of ascertaining the amount of cutaneous exhalation. They enclosed the whole body in a varnished silk bag. There was a small opening to this, which was carefully cemented around the mouth of the subject of experiment. Thus all the moisture from the lungs escaped, while the cutaneous exhalation was confined in the bag. By weighing the body before and after leaving the bag, the total loss from skin and lungs was ascertained. The amount of loss by the lungs was ascertained by weighing the person before he got into the bag and immediately before he left it. After a long series of experiments conducted in this manner, Lavoisier and Seguin found that the mean loss by pulmonary and cutaneous exhalation amounted to 18 grs. per minute, or 2 lbs. 13 oz. in 24 hours. Of this the pulmonary discharge was 15 oz., and the cutaneous exhalation 1 lb. 14 oz. This they regard, then, as the mean amount of daily perspiration. The greatest quantity of matter perspired in a minute, was 26·25 grs. troy, and the minimum 9 grs. Exhalation is increased by fluids, but not by solid food. It is at its minimum during meals, and at its maximum during digestion.

Under certain conditions vapour has been observed to escape from the body in very great quantity. Thus, Haller observed, when in the subterraneous caverns of Clausthal and Rammelsberg, that a distinct cloud or smoke could be perceived rising from the naked human figure.

Some diversity of opinion has prevailed among experimenters as to the gases which pass off from the body in company with the water, by the function of insensible perspiration. Abernethy and Mackensie detected carbonic acid, and Collard de Martigny found nitrogen in addition. These gases appear in variable quantity, and are sometimes altogether absent. After muscular exertion, and after meals, they appear in great abundance. According to Trousset, Barruel, and Ingenhouss, nitrogen is sometimes exhaled without carbonic acid. Monsieur Collard found that the cutaneous transpiration contained most nitrogen when an animal diet had been used, while carbonic acid prevailed when vegetable food was taken. This experimenter also satisfied himself that carbonic acid was evolved from the skin in a gaseous form, and need not be the result of oxydation of carbon by contact with air, as he was able to collect it over water from the skin. The insensible cutaneous transpiration may be regarded then as composed of aqueous vapour, carbonic acid, and nitrogen gases; the two latter not only varying in proportion like the first, but probably being sometimes absent, even in health, according to conditions of the organism, which are not yet sufficiently investigated in relation to this subject.

When, under the conditions referred to at the commencement of this article, the surface becomes covered with sweat, the various matters passing away from the skin by excessive secretion have been examined by chemists with the following results: —

The total solid matters passing away from the unexcited skin have been calculated at about 7 to 8 scruples in the 24 hours, but the very nature of the inquiry prevents any great reliance being placed in such results.

When sweat is collected, as was done by Simon, from persons subjected to the vapour bath, it appears as a turbid fluid, yielding a deposit by standing. This deposit consists of epithelium scales. The clear fluid was found by Simon to possess a specific gravity of 1003 to 1004. This result, however, must be modified continually by the water condensed on the surface from the aqueous vapour of the bath. The fluid was acid, but only very slightly so, and in the course of twenty-four hours it became neutral. The acidity of the sweat was therefore dependent on the presence of carbonic acid. Ammonia was evolved from it after exposure. Simon analysed his own sweat. He found it to develop an odour of ammonia, and could detect that gas by testing with the vapour of hydrochloric acid. On evaporation, the peculiar smell of animal extractive matter was observed. When the dry matter was triturated with potash, ammonia came off. Sulphuric acid added to another portion developed sulphurous acid at first, and afterwards produced a strong odour of acetic acid. In one instance observed by Simon, the sweat gave off the odour of butyric acid so strongly as to leave no doubt on his mind of the presence of that substance. From various experiments, Simon concludes normal sweat to contain —

1. Matters soluble in ether: traces of fat, sometimes including butyric acid.

2. Matters soluble in alcohol: alcoholic extractive, free lactic or acetic acid, chloride of sodium, lactates and acetates of potash and soda, lactate or hydrochlorate of ammonia.

3. Matter soluble in water: aqueous extractive, phosphate of soda, and, occasionally, alkaline sulphate.

4. Matters insoluble in water: desquamated epithelium, phosphate of lime, and peroxide of iron.

Berzelius examined and analysed sweat as obtained from the forehead. He found it to contain much the same substances that exist in the acid juice of flesh. He states chloride of sodium to be in excess, however. The skin is certainly an active excreter of free phosphoric and lactic acids, and assists the urine in its important office of discharging these acids from the system. Landerer has lately shown the presence of urea in healthy sweat, and it is probably by decomposition of this substance that collected sweat becomes ammoniacal. Thus, the skin would appear, under varying conditions, to assume the excretory duties of the lungs and kidneys, and we are almost constrained to regard its function as supplementary as well as complimentary to that of respiration and the excretion of urine.

Anselmino has, perhaps, made the best analyses of the sweat. According to him one hundred parts of the solid matters of sweat contain —

1. Substances insoluble in water and alcohol (chiefly calcareous salts)	2·0
2. Aqueous extractive matter (regarded as salivary matter by Anselmino, according to Berzelius without sufficient reason), and sulphates - - - -	21·0
3. Spirituous extractive (chloride of sodium and osmazome) - -	48·0
4. Alcoholic extractive (osmazome, lactic acid and its salts, regarded by Anselmino as acetic acid and acetates) - - - -	20·0

In order to obtain the solid matters of the sweat, Anselmino collected it in the vapour bath by means of clean sponges. The fluid so obtained was filtered, and the water distilled off. Acetate of ammonia was found in the receiver. Simon considers acetic acid to be a constant constituent of the sweat, and with Berzelius considers hydrochlorate of ammonia to be a normal component of the fluid. Simon, though agreeing in the general with the results of Anselmino, failed to detect sulphates in freshly collected sweat. He found it, however, in the incinerated residue, from which he infers that some of the constituents of sweat contain sulphur.

The following is Anselmino's analysis of sweat in 1000 parts: —

Water - - -	995·00	987·500
Epidermis and calcareous salts - -	·10	·250
Aqueous extractive matter (sulphates)	1·05	2·625
Spirituous extractive, chlorides of sodium and potassium -	2·40	6·000
Alcoholic extractive, acetates, lactates, and free acetic acid -	1·45	3·625

In the ash of the dried residue of sweat, Anselmino found carbonate, sulphate, and phosphate of soda, chloride of sodium, phosphate and carbonate of lime, with traces of iron. In every 100 parts of dry matter of sweat, he found 22·9 of these fixed saline matters.

But little is known concerning the sweat of the lower animals. Fourcroy analysed the white powder which hangs to the coat of the horse when sweat has dried upon it; he detected urea in that substance, but Anselmino could not. According to the latter chemist, the white matter is made up of the following constituents: —

1. A substance of acid reaction, with an alkaline lactate or acetate.
2. Extractive matter possessing the odour of the animal; and chloride of sodium.
3. A brown extractive matter soluble in water and precipitable by infusion of galls. Alkaline chloride and sulphate.

The ash consisted of alkaline sulphates and chlorides, but no carbonates or phosphates; phosphate of lime and magnesia, with traces of oxide of iron.

Sweat in disease. — The sweat in disease has been submitted to examination in a very unsatisfactory manner, but few analyses having been made. Dr. Piutti, of Elgersburg, made analyses of the sweat obtained from three patients who were undergoing the water cure, and obtained the following results: —

1. Patient suffering from chronic gout, sp. gravity of the sweat 1003·5.

Water	995·5
Chloride of sodium	3·0
Phosphate of ammonia	·5
Acetate of ammonia	·5
Hydrosulphate of ammonia	a trace
Extractive matters	·5
	1000·

2. Patient the subject of gout during six years, sp. gravity of the sweat 1004.

Water	993·0
Chloride of sodium	4·0
Phosphate of ammonia	0·8
Acetate of ammonia	0·6
Hydrosulphate of ammonia	a trace
Extractive matters	1·6
	1000·

3. Patient suffering from paraplegia, otherwise healthy, sp. gravity of the sweat 1003.

Water	994·6
Chloride of sodium	3·3
Phosphate of ammonia	1·1
Acetate of ammonia	0·5
Hydrosulphate of ammonia	a trace
Extractive matters	0·5
	1000·

The animal matter possessed a green colour in this case. Soluble in ether, but not in alcohol.

The perspiration in different forms of disease possesses a peculiar odour, and many very fanciful opinions have been given on this point. Scabies is said to afford a mouldy odour; jaundice is musky, and syphilis sweet. In ague, the odour of fresh-baked brown bread is said to pass from the skin. Stark states that the quantity of lactic acid is increased in the sweat in scrofula, rhachitis, and some cutaneous eruptions.

Prout noticed an increase in the quantity of salts in sweat in a case of dropsy. An excess of salts has also been noticed by Anselmino in a severe case of gout. It has been said that in cases of gouty and urinary concretions the quantity of phosphate of lime is increased. As regards the latter form of disease, there is no good reason to believe the opinion above stated to be true.

A great increase of lactic acid is observed in cases of rheumatism and gout; the sweat in such cases is always extremely acid. Anselmino, however, states, that he has observed the sweat *after* a gouty attack has passed off, containing a large proportion of ammonia. Anselmino and Stark state that they have detected albumen in sweat; the former in rheumatic fever, the latter in gastric, putrid, and hectic diseases, and in cases generally immediately before death. Simon could not detect it in sweat which he obtained from the breast of a person suffering from phthisis in the colliquative stage.

Fat is also said to be found in large quantity in colliquative sweats. Bilin and biliary colouring matter, or biliphæin, have been found in the sweat of icteric persons. Berend says he has observed it in bilious fevers.

Voigtel states, that he observed blood to sweat from under the arm of a young man after violent exertion. Such perspiration is also said to have been observed in scurvy and low typhus fever. Uric acid has been found in the sweat of gouty patients, probably in the form of urate of soda.

Landerer observed a red-coloured sweat in a fever patient's axilla, which he believes to have contained the red colouring matter of the urine (uroerythrin). Blue perspiration has been noticed by several writers. Dr. Bleifuss noticed it coming from the foot of a patient suffering from abdominal disease. Michel noticed it in hysteria and hypochondriasis. Sugar has been detected in the perspiration of persons affected with diabetes, by Nasse. Various substances used internally as medicines, as articles of diet, or taken for the purpose of experiment, have been recognised in the sweat. These are, according to Stark, sulphur, mercury, iodine, iodide of potassium, assafœtida, garlic, saffron, olive oil, rhubarb, indigo, Prussian blue, and copper.

Landerer observed, that if he took quina his sweat became bitter.

In cases of Morbus Brightii I have been able more than once to detect urea in the perspiration, and I am inclined to believe it constantly present both in cases of suppression and retention of urine.

I have stated that experiments lately made by Landerer, the Athenian chemist, have proved urea to exist in the sweat in health. If this be proved, we of course can no longer regard it as an abnormal constituent of that fluid, but must look upon it merely as present in excess in the diseases above alluded to.

(*G. Owen Rees.*)

SYMMETRY (συν—μετρον). In its general acceptation this word means a just and harmonious proportionment of parts to one another and to their whole; in anatomy, however, it has a different and more restricted meaning. With its anatomical signification alone I have now to deal, and that may be defined as follows: — Symmetry is a word used to express an idea that would be more correctly represented by a verb than a noun, for it is the idea of not a thing but a fact — the fact, namely, that one half of an animal is usually an exact reversed copy of the other — the right side is a reversed copy, or repetition, of the left. To this there are numerous exceptions, even in the human subject; of which hereafter.

That unreversed *serial* copying or repetition which is observable, for instance, between the scapular and pelvic limbs, is enunciated by the analogous expression *serial homology*. The point on which a distinction may be made between symmetry and homology, is that of the reversing of the copy or repetition as characteristic of the latter. This characteristic seems to impress one with the notion that the two halves are parts of a whole, whereas an unreversed serial recurrence of similar parts inclines one to accord a kind of separate individuality to each repetition. A clear distinction between these two styles of repetition ought undoubtedly to be firmly impressed and maintained on the mind. I have, however, for want of a convenient inflection of the word under consideration, at the risk of some confusion, been long accustomed to use the expression *lateral homology* in reference to symmetrical repetition — and in that sense I shall have to use it in this article.

Whether the word symmetry should be applied to that antero-posterior repetition which is met with in caudal vertebræ of fishes, for instance, is not yet determined by usage, and it will be sufficient for me hereafter simply to make my remarks upon the apparent existence of it. In so doing I shall use the expression *antero-posterior homology* in a sense precisely parallel to that of lateral homology.

Lateral Repetition.—That the right hand and foot, and the right side of the head and trunk, are the exact counterpart of the left is a fact so obvious, that merely to assert it seems an unnecessary truism. It should, however, by no means be regarded as a matter of course. It might have been otherwise.

The human skeleton is, normally, perfectly symmetrical in all its details, and so are the skeletons of all vertebrate animals, with the exception of the Pleuronectidæ, or flat fishes, noticed hereafter. The archetype or abstract ideal figure of an osseous vertebral segment, as that of Prof. Owen, at vol. iii. p. 824., is a symmetrical form. But it is doubtful whether any single bone in the skeleton should be regarded as primordially mesial and symmetrical — whether any ossific point is originally in the middle line. The ideal archetype of the above illustrious author contains three mesial azygos elements, viz. the hæmal and neural spines and centrum; but it has always appeared to me that each of these elements should be represented in the ideal by a pair of pieces, because each of them is occasionally represented in nature by a pair of bones: Prof. Owen, for instance, regards the two parietal bones as the neural spine of a vertebra. Though there is no difficulty in conceiving the coalescence of any number of pieces into one, and though it is easy to conceive that this coalescence may have occurred before the commencement of ossification, so that two or more of the points destined to become the centres of the ossifying process may be brought so close together as, when manifest by the earthy deposit, to appear but as one, yet it is not possible to conceive that two pieces can be developed from one ossific point. The single azygos condition may proceed from the double, but the double cannot proceed from the single; therefore the double condition must be regarded as the primordial, and should hold place in the abstract type. There are occasionally met with certain monstrosities which seem to show in a remarkable manner that a vertebra is composed of two lateral halves that are primordially separate. Thus, in double-headed monsters, wherein there are two vertebral columns above, which coalesce and form one below, the half of each of the two columns which is adjacent to the other seems to be lost at the point of coalescence, and the single column below this point seems to be composed of the right half of the one and the left half of the other of the two columns. In the skeleton of the Boa Constrictor preserved in the Hunterian Museum, there are two vertebræ that are double on the right side and single on the left, bearing two ribs on the right side and only one on the left; or rather there are two specimens of right halves of vertebræ, existing independently, which are anchylosed, the one to the vertebra in advance of it, the other to the one behind it. This anchylosis alone justifies the expression "vertebræ double on the right side;" but in neither instance is it so complete as by any means to mask the real nature of the independent half vertebra. Such facts as these, especially the existence of one half of a vertebra without the other, even seem, in contradiction to the impression stated above, to claim for each half of a vertebral segment the importance of a separate individuality, such as is accorded to each vertebral segment itself. They seem to show that a vertebra is as much a compound of two lateral parts symmetrically repeating one another, as the human spinal column is a compound of thirty-three serial repetitions of vertebræ. The fact of the lateral halves being *reversed* copies of one another, I am disposed to regard as proof of their being parts only of a whole, and as disentitling them to an individuality like that which we are accustomed to assign to unreversed serial repetitions; it may, however, be regarded as not sufficient proof of this. The value to be given to such facts depends, here as elsewhere, upon the peculiar bias of different minds, and the associations that pre-occupy them. It is not necessary in the present state of our knowledge, nay, it is not expedient, to bind the mind down to this or that view of the facts that come before it.

A remark, *en passant*, is due to the consideration that the corresponding organs and parts of organs of the two sides are not only similar in form and structure, but normally of exactly the same age. The corresponding ossific points of each side make their appearance at precisely the same time, and in all respects the original development and subsequent evolution and maturation of the embryo proceed exactly *pari passu*. The exceptions alone to this rule of symmetry will chiefly occupy our consideration.

In *Man*, except perhaps in the very early stages of his existence, exceptions are offered by the heart, great blood-vessels, lymphatics of the trunk, lungs, bowels, liver, spleen, and pancreas, with their appendages. All these parts were in all probability, in the very earliest stages of the embryo, symmetrical; most of them have been proved by actual observation to have been so; it is, however, difficult to conceive this to have been the case with the following other instances of departure from symmetry.

All decussations in the middle line are a-symmetrical. Indeed, if a fibre crosses the median line anyhow but at right angles, there is a departure from symmetry. Consequently, the decussation of the optic nerves, the decussation of fibres in the medulla oblongata, and the decussation of white fibres at the linea alba, are instances of exceptions to symmetrical repetition. One is tempted, in the last instance especially, to believe that these decussations are not in the original embryonic pattern or plan; but that they are developed subsequently, in obedience to subsequent circumstances: the knowledge of the power which circumstances, external or internal, existing at any period of an animal's life, have in modifying the directions of fibres of areolar tissue, and of affecting it in other ways, aids one in this belief.

The most remarkable of the above instances, and that in which the primordial symmetry is most widely departed from, is the *heart and the great blood-vessels* that are immediately connected with it. The heart first makes its appearance as a mass of cells posited in the middle line, which soon becomes hollow and divided into three compartments, the lower one of which receives the embryonic veins, and is therefore the auricle, whilst the upper one is the commencement of the aorta, or bulbus arteriosus. The middle cavity (the ventricle) becomes bent into a horse-shoe form, so as to bring the auricle and bulbus into apposition. From the latter proceeds a median artery, giving off six arches on each side that surround the space occupied by the digestive canal and converge towards the spine, where they are received by two symmetrical aortæ. The vein that enters the auricle is a canal or sinus, that intercommunicates between two venous trunks symmetrically placed on each side of the spine, called ductus Cuvieri, the posterior continuation of which is the cardinal (future azygos and hemi-azygos) veins; and the anterior, the jugular. One of these ductus is permanent as the superior cava. The omphalo-mesenteric vein, which empties into the auricle, is at this time situated in the middle line between and in front of the cardinal veins, and into it falls the single mesial vena cava descendens. The precise periods at which these parts are first discernible, and those at which the changes about to be described take place, will be given in the article OVUM. It is the manner of their metamorphosis alone that bears upon this present inquiry. So far all is symmetrical; now commence those changes whereby the adult impar arrangement is eventually effected. The fourth and fifth (from the heart) pairs of aortic arches (the two anterior pairs), and the *right* one of the second pair, soon disappear. The *left* one of the second pair is permanent as the arch of the aorta, and the third pair persist as the subclavian arteries. The first pair give off branches to the nascent lungs. Meantime, the lower (abdominal) parts of the aortæ have coalesced, and those parts of them which intervene between the second arch on the left side (the arch of the aorta) and the third (the left subclavian), and between the first arch of the right side (right pulmonary artery) and the third (right subclavian), disappear. Now we have, on the *left* side, the first two arches uniting behind to form the left aorta. The first gives off a branch to the lungs, and that portion of it which is beyond this pulmonic branch remains, as the ductus arteriosus, pervious till birth; whilst that portion which is nearest to the heart remains, in connection with the pulmonic branch, permanent for life as the left pulmonary artery. On the *right* side the first arch alone, the second having previously disappeared, forms the right aorta, which soon joins its fellow with which it coalesces below. The proximal part of this arch is permanent, and remains in connection with its pulmonic branch as the right pulmonary artery, whilst the part of it beyond the pulmonic branch, together with its continuation, the right aorta, down to its point of junction with its fellow, soon disappears. A septum, meanwhile, has been developed in the ventricle of the heart, dividing it into right and left ventricles, and an imperfect one in the auricle. The bulbus arteriosus also has been divided by a septum, in such a manner that the first pair of arches remains in connection with one division of it, which communicates with one of the ventricles, whilst the permanent left arch of the second pair communicates with the other division, and through it with the other ventricle. It is most probable that these septa, when first developed, extend from side to side, consequently that the systemic ventricle and aorta are at first in front of the pulmonary ventricle and artery, and that the heart subsequently undergoes a twist towards the right, carrying the systemic ventricle round behind to its permanent position on the left. In reptiles, in which a great many other of the mammalian fœtal characters are permanent, the root of the systemic is in front of that of the pulmonic artery, and there is not that twining round one another of the great arterial trunks which is met with in man. Thus, then, these, the most unsymmetrical parts of the whole body, can be proved by actual observation to have been originally perfectly symmetrical, and the manner of their attainment to their ultimate unsymmetrical form can be accurately traced.

The a-symmetry of the *lungs* is little more than a trifling difference of size between the two, dependent upon the encroachment of the heart by its displacement towards the left. And the a-symmetry of the great abdominal viscera enumerated above, and of their appendages, depends entirely upon lateral displacement and excesses of growth of one side over the other, having reference to convenience of packing. This a-symmetry, greater in mammalia than in reptiles and fishes, on account of the presence of the diaphragm, which, so to speak, thrusts the abdominal viscera downwards, necessitating lateral displacement, attains its acme in man, owing to the great lateral measurement compared with the antero-posterior distance which is so conspicuous in his figure when contrasted with that of other animals. The hepatic attachments of the falciform ligament and gastro-splenic omentum landmark the original median line of the *liver;* and that larger part of it which is to the right of the ligament and behind the omentum, is the right lateral homologue of that lesser part which is to the left of the ligament and in front of the omentum. The *gall-bladder* appears to be an unsymmetrical organ, situated to the right of the median line. I am unable to state whether or not a left gall-bladder has once existed and been suppressed, or whether it is a diverticular production of the gall-duct evolved subsequently to the first sketching of the embryo; or, lastly, whether it is originally median and subsequently displaced. The anterior wall of the *stomach* is the left lateral homologue of the posterior wall. The *spleen* is an originally median organ, situated in the originally median meso-gastrium. The *great omentum* is a pouching out of the meso-gastrium towards the left, consequently its outer surface is the left lateral homologue of its inner surface.* The *pancreas* is an originally median organ, one end of which has been displaced along with the pylorus towards the right, so that its anterior aspect is the left lateral homologue of the posterior. The *intestinal canal* can be witnessed in the embryo as a straight, uniform, mesial, and symmetrical tube, until its length having become greater than that of the region which it is destined to occupy, it is compelled to arrange itself in gyrations and loops. The posterior and anterior walls of the stomach were originally, as indicated above, its right and left halves; and as to the other parts of the alimentary tube, whatever difficulty there is in recognising the manner of their displacement in the human subject, is at once dispelled by examining their condition in the lower animals. No difficulty whatever is encountered in respect of the small intestines, for their mesentery is attached nearly in the median line; the bowels themselves, however, are continually varying their position, relative and positive, according to the manner of packing most convenient for their variable contents. Not so easy is it to understand the kind of displacement which has taken place in respect of the large intestines. The *colon* is curled back, and crosses over the small intestine from right to left, forming a loop. In the human subject, the true relation of these parts is further masked by the singular circumstance of this crossing over occurring just at the point where the meso-gastrium, after having descended as the great omental bag, is returning to the spine, and the colon, finding it there, so to speak, avails itself of it, and uses it as a mesentery; anatomists have named this borrowed portion of the meso-gastrium the transverse meso-colon. In Ruminants the colon, being exceedingly long, avails itself also of the mesentery of the small intestines, into which a *loop* of it is thrust further and further until it makes three turns; so that in tracing the colon onwards with the finger, you make three spiral turns in the mesentery, and then double and return by three spiral turns placed between the former spirals.* On the other hand, in the Carnivora, where the colon is very short, it crosses over the lower end of the ileum so near to its termination that it is evident that the next degree of shortening must result in the continuation of the small and large intestines in a straight line. This actually takes place in the Reptilia †, and then there is no longer any difficulty in recognising the original mesial and symmetrical position of the intestinal tube and its appendages, so displaced in the human subject as to make this recognition so extremely difficult.

It is by no means uncommon to meet with instances where all the unsymmetrically posited organs of the human body are placed completely *vice versâ* to their usual situations; the heart pointing towards the right; its pulmonic to the left of its systemic ventricle; the vena cava to the left of the aorta; the liver in the left, and the spleen in the right hypochondrium; and the cæcum in the left iliac fossa. Almost every anatomical museum contains an instance of this kind; and in all instances where the history of the case before death was known, the average health

* See Peritoneum.

* See Ruminantia.

† See *fig.* 491. Vol. III. Peritoneum.

and ordinarily well-developed state of the subject attested the insignificance of this transposition in respect to the well-being of the individual. Such cases are most interesting from this consideration,—that *all* the unsymmetrical organs are transposed. There is, I believe, no instance on record of one, or two, or less than the whole of the unsymmetrical organs occupying the side which is not their usual one. This prompts the belief that the side which these organs shall respectively occupy is determined by a single impulse first given to one of them.

Abnormal deviations from symmetry are of extremely frequent occurrence. The blood-vessels of the body are very rarely perfectly symmetrical. In the adult subject the two sides of the body rarely match exactly in external form. The right hand is usually larger than the left. Accidental circumstances occurring to an individual frequently disturb the symmetry, but it is by no means uncommon to meet with evidence of hereditary transmission of aberrations from symmetry. Such monstrosities as supernumerary fingers and toes are sometimes symmetrical, but just as frequently, perhaps more frequently, the monstrosity exists on one side alone.

Comparative Anatomy.—I pass on now hastily to notice such deviations from symmetry as are met with in the normal conditions of the lower animals belonging to the vertebrate sub-kingdom, and to examine the question of symmetry in the other sub-kingdoms.

In all *Mammalia* there is much the same departure from symmetry in the viscera of the chest and abdomen as is found in the human subject ; but in no other mammal is the lateral displacement so great as in man, for in all others there is a greater proportionate antero-posterior depth of chest and belly. The only other notable instances of a-symmetry known to exist in the mammalian class are the following: — In the male narwhal or sea-unicorn the left front incisor tooth attains the enormous length of eight or ten feet, while the right one is found as a rudiment that never pierces the gum. Spirals in the middle line are departures from symmetry ; consequently the spiral penis of the boar, &c. must be regarded as instances of a-symmetry ; a slight excess in length of one of the halves is sufficient to produce this spiral form. The left nostril of most of the Cetacea is constantly much larger than the right.

In *Birds* there is much the same want of symmetry in the viscera of the trunk as is met with in mammals. The right one of the second pair of embryonic aortic arches however is retained instead of the left, so that the adult *aorta* arches over the *right* bronchus. But notwithstanding this, the left ventricle is the systemic one, and presents the same excess over the right, in the thickness of its walls, as in Mammalia. Both of the ductus Cuvieri are retained and form two *superior venæ cavæ*. The *liver* is situated mesially, that is to say, its great fissure and falciform ligament are in the middle line ; but its *left* lobe is usually the larger, and in the common fowl presents a fissure which is not repeated in the right. The *œsophagus* diverges slightly towards the *right*, but the cardiac orifice of the *stomach* is to the left of the pyloric. The long loop described by the *duodenum*, and the *pancreas* which is surrounded by it, are found extending diagonally across the abdomen in front of the other bowels, their extremity resting in the left iliac fossa, but they are not fixed in this position. The *gall bladder* is situated as in Mammalia. There being no great omentum, the *spleen* occupies its typical position behind the stomach. There is usually a disparity in the length of the pair of cæca met with in this class.

But the most remarkable exception to symmetry in the class Aves is that which exists in the *female generative organs*. The left ovary and oviduct alone are functionally evolved, whilst the right, becoming atrophied at an early period, are barely traceable in the adult animal. A few instances are on record where these right lateral homologues of the ovary and oviduct have been found evolved in functional size as a testicle and vas deferens, thus forming lateral hermaphrodism.

The *male generative organs* of birds are all symmetrical except the penis, when it exists, which is spiral.

Another instance of want of symmetry is presented by the beak of some birds, as the cross-bill, &c.

Reptiles. — The heart of reptiles is situated in the middle line, but it is not symmetrical in form, nor do the great blood-vessels enter and quit it in a perfectly symmetrical manner ; they however approach more nearly to symmetry in this class than in any of those which have been previously considered. In all reptiles there are at first two aortæ, symmetrically disposed, arching over the right and left bronchi respectively, and uniting with one another to form one trunk on the spine. The vessels given off from these are, however, most generally not symmetrical, the head and front limbs being supplied frequently from the right arch alone, and the chylopoietic viscera from the left alone. The pulmonary arteries arise behind the origin of the aortæ. The lungs of reptiles are usually two symmetrical organs, but in the Ophidia the left lung, when it exists, is much shorter than the right, and in some, as Coluber thiringicus, it is wanting altogether, the only vestige of it being a cæcal depression on the left side of the lower end of the trachea ; this absence of the left lung entails, of course, the loss of the left pulmonary vessels.

The stomach and bowels of the Chelonia, owing to the flattened form of the animals, are nearly as much laterally displaced as in the human subject. In the other reptiles they are not much out of symmetry, yet in none are they exactly symmetrical. The cardiac end of the stomach tends, though often but a little, towards the left ; the pyloric is free, and can be brought without violence to the middle line, but yet it is always found leaning to the right. This renders the spleen more conspicuous on the left. The liver of reptiles extends from side to side, but the right lobe is the largest.*

In the tadpoles of toads and frogs, I have observed that there is no gill opening on the right side. In the Lepido-siren the anus is situated on the right side of the mesial ridge of the tail.

Fishes. — The heart of fishes is posited symmetrically, but the relative position of the auricle and ventricle is usually unsymmetrical, the former being behind and to the *left* side of the latter. The single arterial trunk, with its branchial arches and the coalescing aortæ, however, are precisely alike on both sides. The intestinal canal, being generally much longer than the abdomen of the fish, is necessitated to throw itself into unsymmetrical loops and convolutions.

There is a very remarkable departure from symmetry in all the members of the group of fishes called *Pleuronectidæ*, or flat fishes, such as the turbot, halibut, sole, and flounder. These fishes lie at the bottom, and swim, on one side; and the side which they keep uppermost is coloured dark like the back of other fishes, whilst that which they keep undermost is white like another fish's belly. The dark-coloured side is also somewhat convex, whilst the white side is nearly flat. The dorsal azygos fin is continued on to the head, beyond the eyes, almost to the muzzle, and, what is most remarkable of all, both the eyes appear on the dark side, and are actually both situated on one side of the dorsal azygos fin. With the exception of the different colour of the skin, the different degrees of convexity of the two sides, and a slight distortion of the mouth, the whole of these fishes are symmetrical in all their parts, besides the eyes and the structures immediately surrounding them. The bones immediately contiguous to the eyes suffer the following remarkable distortion :— The occipital bone is almost perfectly symmetrical, and its mesial crest is continued far forward as a sagittal crest between the parietals in the real as well as the apparent middle line, supporting the styliform bones to which the rays of the dorsal azygos fin are articulated. There is a slight difference in the size of the parietals, that of the right or white side being the largest ; but it is the frontal and pre-frontal bones that suffer the greatest distortion. Arriving at the frontals, the real or primordial middle line is suddenly deflected towards the left or dark side, whilst the sagittal crest, still supporting the azygos fin, is continued straight on, on the right frontal alone. The left frontal is less expanded, but more clumsy than the right, and extends forwards in a curved form between the eyes, presenting a concavity towards the right. To this concave curve is sutured a falciform process produced from the left anterior corner of the right frontal, which is quadrate. This suture of course indicates the real middle line. The eyes are situated on each side of the septum thus formed. The end of this compound septum rests on the suture between the two pre-frontals, and this suture, which again indicates the real mesial line, presently regains the apparent middle. The right pre-frontal is much larger than the left, and comes again into contact with the right frontal on the *outside* of the right eye, which therefore occupies an orbit with a complete bony margin, whilst, the same thing not occurring on the left, the eye of that side has no orbit, but seems to lie loose in the soft structures of the cheek. The symmetry of the base of the skull is disturbed but slightly, the long sphenoid and vomer forming nearly a straight line, and participating but slightly in the abrupt deflection of the middle line which takes place above. Not the least curious part of this history is the non-participation of the dorsal azygos fin in the deflection of the mesial line : it furnishes an additional proof that its rays are not a part of the endoskeleton. The eyes of the pleuronects are of different sizes ; the furthest from the dorsal fin (the left, the one that has no orbit) being the smallest, and the optic nerve and optic lobes of the brain, which belong to it, are smaller than their fellows.*

In using the terms right and left in the above descriptions, I have constantly had in view the turbot, which is coloured, and shows its eyes on the left side; but the sole, dab, and flounder, are coloured on the right, and therefore those terms must be reversed when applied to them. It is extremely common to meet with individual specimens of Pleuronectidæ coloured, so to speak, on the wrong side, that is to say, not on that side which is usual, and the rule for the species. Turbots coloured, and having their eyes on their right sides, are frequently met with, and the flounders brought to the London market are almost as frequently coloured, and show their eyes, on the left as on the right side. The unsymmetrically posited intestines of these fishes do not participate in this transposition, but occupy, respectively, the same sides in the monstrous as in the normal individuals. The frequency of these monstrosities tempts one to conjecture that external circumstances may, perhaps, determine which side of the pleuronect shall have the eyes and be coloured.

Articulata. — The animals composing this sub-kingdom are bilateral and symmetrical. The abstract pattern or type of an articulate animal, like that of the Vertebrata, is a symmetrical figure.† From this primordial symmetry there are but few deviations, and those exceedingly trifling in amount.

Amongst the *Entozoa*, the English tapeworm (*Tænia solium*), if the flat sides be taken as dorsal and ventral, presents an instance of a-symmetry in the position of its genital orifices, which are situated on the edge of each joint, sometimes on one side, sometimes on the other, indifferently.

In the Natural History series of the Mu-

* Vol. IV. fig. 220. p. 304. art. REPTILIA.

† Vol. I. Fig. 378. art. CRUSTACEA.

seum of the College of Surgeons (No. 205.), there is a portion of a tænia lata, which exhibits a monstrosity very interesting in its bearing on the question of the individuality of half segments (p. 845.). On one side, which for distinction we will call right, there are three half segments, the middle one of which unites with two half segments of the left side, leaving the upper and lower of the three right halves isolated and independent. One of these contains a generative apparatus.

Mollusca. — In this sub-kingdom absence of symmetry seems to be the rule — its presence the exception. There are great practical difficulties in the way of finding an abstract notion or type of a mollusk such as have been found for the Vertebrata and Articulata. If, however, such type be symmetrical, that symmetry is departed from much oftener than it is preserved. There is no appearance in any mollusk of a serial repetition of parts — nothing like serial homology, except in the Chitons, whose shell consists of a number of similar symmetrical transverse bands. The highest class of mollusks, the Cephalopoda, are symmetrical, and when they inhabit shells, as the Argonaut and pearly Nautilus, their shells are symmetrical. But the enormous number of species comprised in the classes Gasteropoda and Acephala are nearly all unsymmetrical. The slugs are the most symmetrical of the Gasteropoda in their external form, but here the air-orifice, for instance, is on one side.

Radiata. — For convenience of illustration, I select from among the animals composing this sub-kingdom the common star-fish. (Figs. 16, 22, &c. Vol. I. Art. Echinodermata.) This animal presents to our view a flattened form with five exactly similar rays or arms radiating from the centre, where is posited the mouth. Around the mouth is a nervous circle consisting of a number of ganglia corresponding to the arms, connected with each other by intercommunicating cords. Each arm is symmetrical in itself. Now this figure may be divided into two symmetrical halves by a line drawn across it in either of five different diameters. What is to decide which of these is to be regarded as the mesial line? Fortunately there is, on the side which is the reverse to that on which the oral orifice is placed, a peculiar spot, the remains of an embryonic structure, which is not in the centre, and will therefore serve for a datum. In certain other echinoderms the anus is situated eccentrically, in which case it also may be taken as a datum. But still a line drawn through either of these, the number of the arms not being an even number, will divide one of them in its middle on one side, and pass through the interspace between two of them on the other. This, as the arms are exact repetitions of one another, seems an unnatural and arbitrary proceeding. Still, though it possesses no natural middle line, and consequently is not bilateral, yet is the star-fish a symmetrical animal, for the idea of bilateralism is by no means included in our definition of symmetry.

Whenever a number of exactly similar parts symmetrical in themselves are arranged around a centre, whether their number be two, as in bilateral forms, or five, as in the star-fish, the whole figure is symmetrical. Abandoning then the idea of bilateralism, we may look upon the star-fish as composed of five repetitions arranged around a centre. Regarding it in this manner, we are able to institute a comparison between the form of the star-fish and that of the segmented vertebrates and articulates. The star-fish may be regarded as analogous to one segment of a vertebrate or articulate — an animal with one vertebra.

I use the term "analogous," and not "homologous," because the relation called special homology cannot be demonstrated, in any instance, between animals belonging to different sub-kingdoms. The head, the legs, the brain of an articulate, are only functionally the head, legs, or brain. They perform the same function as, but they cannot be shown to be homologous with, the head, legs, or brain of a vertebrate. Indeed I have long held that the sub-kingdoms should be limited by reference to special homology: all animals among which homologies can be pointed out — which all conform to the same type — should be grouped together to form a sub-kingdom.

The view of the analogy of a radiate animal to a vertebrate or articulate animal just given, is considerably strengthened by the manner of development of the common medusa. The larva of the medusa is a polypiform living thing, anchored by one end and tentaculated at the other. This, after a while, becomes marked with numerous constrictions, like a segmented animal, which constrictions become more and more deep until they completely divide the quondam polypiform being into a number of pieces, each of which becomes a perfect medusa. Here is a segmented animal, each of whose joints becomes an independent radiate individual; ergo, each individual is analogous to one segment of a vertebrate or articulate.

Towards a different view tends the fact, that though five, or a multiple of five, is usually the number of the rays of the star-fish, yet there are some members of the same group the number of whose arms are neither the one nor the other; for instance, there are eleven and twelve-armed asterias. Now there is such perfect constancy in the number of the parts of vertebrate and articulate segments, that that constancy seems an integral element of the idea of an archetype. There is, however, no constancy in the number of the vertebrate or articulate segments that go to constitute an animal, and therefore some may regard each arm of an asteria as analogous to a vertebra; — the common star-fish, as composed of five analogues of vertebral archetypes arranged in a circle, — as a segmented animal bent upon itself, with its anterior and posterior extremities adherent to one another. Which of these two views is the correct one — whether either is correct — can be decided then only when the true import of serial homology and of symmetry is definitely ascertained; when it is determined what is due to division, what to radiation, or whether division and radiation, one, or both, or neither, are concerned in their causation.

The skeleton of the *Velella* presents an instance of departure from symmetry, mainly in the oblique set of its vertical plate. The common medusa has a circular outline, and exhibits four quarters, which repeat one another exactly, so that it seems to be marked with a right-angled cross. The horizontal plate of the skeleton of Velella is distorted to a sub-rhomboid form, and marked with two diagonal seams that cross one another obliquely. The longer one of these diagonals is produced upwards so as to form the oblique sail-supporting vertical plate, which also presents a seam continued up from the point of crossing of the diagonals, indicating that it is composed of two parts uniting at this central point. This de facto unsymmetrical radiate is therefore easily reduced in idea to its primordial symmetry.

Infusoria. — Out of the vast number of various forms met with amongst these animalcules the greater number are symmetrical. This symmetry is usually not bilateral, but that of the star-fish. There are, however, some forms which are quite irreconcilable with symmetry, which no line can divide into two similar halves, which are one, and present no repetitions of parts; except, indeed, when they are undergoing fissiparous generation.

Antero-posterior Symmetry. — By reference to the diagram at page 824. Vol. III. Fig. 433., representing the abstract notion or type of a vertebral segment, it will be seen that the upper or posterior half is a reverse of the lower or anterior. Referring to what really exists in nature, we find, in the caudal vertebræ of fish, that their dorsal and ventral halves are counterparts tolerably exact, yet that exactness is not nearly what exists between the lateral halves. If an antero-posterior as well as a lateral symmetry be admitted, then we have four repetitions arranged around a centre. At all events there is here, in the Vertebrata, some amount of evidence of radiation or divergence from a central axis comparable in some degree to what we see in the Radiata. The anterior and posterior parts of vertebral segments, as found in nature, are usually extremely dissimilar. The rays of the dorsal and abdominal (anal) azygos fins of fishes are antero-posterior repetitions, but the fan-like tail fin, which in most fishes seems to be remarkably symmetrical antero-posteriorly, half of it apparently belonging to the dorsal and the other half to the abdominal moiety of the fish, usually belongs, as I have observed in the typical fishes, cyprinoid, &c., in reality, entirely to the abdominal or under moiety. The embryo of these fishes at first has a tail like an eel, into which the spinal column is continued nearly to its tip. A little way from the extremity of this, on the abdominal aspect, a group of fin rays are soon observed to sprout out meanwhile that the end of the vertebral column shrinks and turns up. The group of fin rays grows, and the vertebral column shrinks, so that in time the former is brought to form the fan-like extremity of the animal; but even then the atrophied end of the vertebral column may be detected occupying the upper edge of the fan. Even in the adult fish some trace of this original relation of the tail fin can be detected. If the tail of an adult homocercal fish be macerated or boiled, and all the pieces which are not anchylosed to it be removed, what remains will not be symmetrical, but will terminate by turning or cocking up. Even in the Pleuronectidæ, whose tails seem to be remarkably symmetrical, and where the spinal column seems to terminate in a flat triangular piece, it will be found that the lower half of this piece can be easily removed, whilst the upper half forms one piece with the body of the last vertebra, with which, in fact, it forms a coccyx composed of numerous degenerated and consolidated vertebræ.

Symmetry of Disease.—This subject has been most ably treated by Dr. W. Budd *, of Bristol. Those local diseases, the cause of which is in the blood, usually affect the solids of the body symmetrically. This can be often well observed in lepra, psoriasis, secondary syphilis, gout, and rheumatism, and in the eruption caused by taking the iodide of potassium. It is due, no doubt, to the symmetrical disposition of those tissues for which the morbid poisons have a peculiar affinity. It proves, moreover, that there is more of peculiarity in certain parts of organs than what meets the eye, which peculiarity is symmetrical. For, though the tissue of all parts of a bone, for instance, shall be exactly the same, it shall be diseased at a certain part only, and the disease shall be repeated in exactly the same part of the corresponding bone of the opposite side. Connected with this is the observation made above, that the corresponding points of both sides of the body are exactly of the same age — have reached a certain stage of development at exactly the same time. But the force of this observation in explaining the symmetry of disease is considerably weakened by another fact noticed by Dr. W. Budd, namely, that the diseases above named are apt also to localise themselves in parts that are serially homologous, or corresponding in the upper or lower limbs, as the knee and elbow, wrist and ankle; for these parts, though homologous, are not of the same age. It is well known that the development of the upper and lower limbs does not proceed *pari passu*. There is here, at least, some determining agency more mysterious than mere age. Still more curious and mysterious is the relation of the eruption called shingles to the bilateralism of the body. It often extends zone-like around one half, stopping exactly at the median line before and behind,

* Medico-Chirurgical Transactions for 1842.

and thus seemingly affording evidence of that individuality of one half of the body which was spoken of as a feasible opinion above.

PLANTS. — The leaf of the higher plants, which is the unit or individual of botanists, is bilateral and symmetrical — always in idea, generally in fact. These leaves are associated together to form buds, branches, flowers, or fruits, in whorls. Symmetrical figures are often produced by these associations, but yet the pattern is spiral. In watching the development of spores of conferva, they are seen, whilst still but single cells, to shoot out in various manners, the majority of which are quite irreconcilable with symmetry, either bilateral or radiating. Whatever may be its import, it is quite certain, from the very nature of symmetry, that the cause of it must be internal, that is to say, within the body in which it is manifested. But it has been conclusively determined, by experiments, that external influences, acting upon them in certain directions only, such as light, heat, and gravitation, exert a considerable power in determining the form of vegetable productions. Animals, doubtless, are also greatly affected by these agencies, yet, as they enjoy the faculty of locomotion whereby all parts of them are successively turned towards the directions from which these forces emanate, the form impressed upon them by internal causes, suffers little or no distortion therefrom; but plants, being destitute of locomotion, continually receive these influences in a partial manner, and consequently we the less expect to meet with symmetry among them. Whenever their internal forces tend to make them symmetrical, the partial action of external agents is apt to disturb their symmetry. It is this, probably, that renders the germinating conferva cell unsymmetrical.

CRYSTALS of unorganised matter are spoken of as symmetrical. The symmetry, however, which they exhibit is not a bilateral symmetry. It consists of the repetition of the same angles and facets at the poles of an axis, but the repetitions are not reverses. The reader may illustrate my meaning by cutting a rhomboid in paper, when he will observe that each of its angles and sides are twice repeated, but he will find it impossible to fold it so that one half shall coincide with the other.

The precise import of the symmetry of organised bodies is, as repeatedly indicated above, as yet involved in mystery. Albeit a fact so evident, so constantly obvious to our senses, as often, like gravitation, to pass unheeded, it is a great and an important fact, — a fact of the same order with those which have already led to the establishment and demonstration of grand, comprehensive, and unassailable theories — the bright triumphs of the human intellect, that have reduced to order, simplicity, and connexion, what before was all confused, complicated, and disjointed, — a fact, therefore, that inspires us with hope for our, as yet, imperfect science of anatomy. It seems to tell of radiant forces, of certain, definite, mathematical, and inexorable laws, concerned in the production of animals. Taken with the other important fact — serial homology, it seems to suggest for the development of Vertebrata and Articulata the multiplication of centres in a serial line — of centres of radiant force, that then proceed to induce the surrounding particles to arrange themselves in a symmetrical figure. In truth, as the mind contemplates this fact, various theories pass before it, yet shadowy, changeable, and indistinct as a phantasmagoria. One day, perhaps, some one of these shall meet with definite enunciation and clear demonstration; at present we must be content with putting the fact of symmetry prominently forward and exhibiting it in various points of view, with declaring it an important fact, and not a matter of course.

(S. R. Pittard.)

SYMPATHETIC NERVE.—(See SUPPLEMENT.)

SYMPATHY (*συν-παθος*).— Sympathy may be defined as the assumption by different individuals, or by different parts of the same individual, of the same or an analogous physiological or pathological state at the same time, or in rapid succession. It is popularly known that the act of yawning, performed by one individual in a company, is apt to induce in many of the others an irresistible tendency to the same act. In a similar manner, the excitement of certain emotions (mirth or sadness, laughter or tears) is apt to spread through an assemblage of persons with extraordinary rapidity. The power of eloquence, of music, or of spectacle, to produce such effects, is witnessed every day in places of public resort, whether for devotion, business, or amusement.

Many instances are known in which convulsions have been excited in persons not previously subject to them, by the sight of a patient in an epileptic fit. And peculiar nervous disorders, of a convulsive kind, have been found to affect nearly all the members of a community without the slightest evidence of their being contagious or infectious. An impression upon an organ of sense may produce effects very different in their nature to any thing which could be anticipated; and these many be purely of a physical kind, or they may act primarily upon the mind. Thus certain odours will induce syncope in some people; and the smell of a savoury dish to a hungry person, or even the mention or the thought of a meal, will excite a flow of saliva. The emotion of pity excited by the sight of some object of compassion, or by a narrative of a mournful kind, will produce a copious flow of tears.

All such phenomena are said to result from Sympathy. When one yawns, immediately in consequence of another's yawning, the former evidently and truly sympathises with the latter; and the convulsions which are induced by the sight of another in a fit, are not less sympathetic. The individual in whom the convulsions are induced, sympathises with the other. Such obvious instances of sympathy between different individuals led to the supposition of some such similar consent between different or even distant parts in the same person.

Motions or sensations caused in certain parts, in consequence of a primary irritation of other and distant parts, are of the sympathetic kind. These motions or sensations are produced in, as it were, an indirect or circuitous manner, or one different from that in which they are ordinarily excited.

Thus a stimulus to the olfactory membrane causes a peculiar affection of the sense of smell, and occasions that depression of the heart's action, from which results a state of syncope. Or another affection of the same sense causes a suddenly increased action of the salivary glands.

If we analyse any one of these examples of sympathetic actions, it will appear that three circumstances may be noticed in the production of the phenomena: 1st, the primary exciting cause, which may be an object presented to the mind through one of the organs of sense, or causing an impression upon any sensitive nerve, and therefore upon some part of the centre of sensation; 2ndly, the part affected directly by this primary stimulus; and, 3rdly, the action or sensation resulting from the affection of this part.

Many other sensations or motions may be enumerated besides those above referred to, whether occurring in health or in disease; and we shall give examples of these before we discuss this subject further.

The examples of sympathetic *sensations* which may be adduced are chiefly of the morbid kind. Pain is felt at a certain part, in consequence of an irritation in another part distant from it, and apparently altogether unconnected with it. A familiar instance of this is pain in the knee from disease of the hip-joint. So marked in some instances is the pain in the knee, and so much has it absorbed the patient's attention, that the real seat of the disease has been overlooked, and the remedies been applied exclusively to the knee. Pain in the right shoulder, from disease of the liver, is a sympathetic sensation of similar kind; and sometimes the hepatic irritation causes pain over a more extensive surface. Whytt mentions, that, in two cases of suppuration of the liver, he had seen the patients "affected with a numbness and debility of the right arm, thigh, and leg." Sometimes both shoulders are the seat of pain, from hepatic irritation.

The peculiar sensations felt in the teeth from a noise which grates upon the ears, is sympathetic of the irritation of the auditory nerve. Practitioners are well aware how many morbid sensations in parts remote from the intestinal canal may be cured by the removal of scybala or other accumulations from it. Painful affections of the nerves of the face, and of other parts, are often due to a cause of this kind. The irritation of a stone in the bladder gives rise to pains in the thighs, or to itching at the end of the penis; and uterine irritation, whether from disease or from the enlargement of that organ in connection with the early stage of pregnancy, causes similar pains in the nerves of the thighs.

Headache and defective vision are frequently produced by disordered stomach. A draught of very cold water, or ice, taken quickly into the stomach, may occasion acute pain in the course of either frontal nerve. This same nerve on one side is frequently the seat of pain after the imprudent use of acid wines or other fermented liquors.

Movements, excited by the operation of a stimulus applied at a distance, form a large proportion of the instances of sympathetic phenomena. All the ordinary physical nervous actions in which motions are excited by stimulating a sentient surface, may be regarded as examples of sympathetic actions.* The contraction of the iris upon the application of the stimulus of light to the retina, or of the pharyngeal muscles by stimulating the mucous membrane of the fauces, are instances in point where the stimulus acts indirectly upon the contracting fibre. Nothing is more sure than that in these instances the change wrought by the stimulus in certain sentient nerves, travels by a circuitous route through a nervous centre to the muscles which are called into action. Akin to these actions are the forcible respiratory movements which may be excited by irritation of the tracheal membrane, as coughing; or sneezing, by stimulating the nasal membrane; or vomiting, by irritating the fauces. Spasmodic affections are often instances of morbid actions in sympathy with intestinal irritation, or the irritation of teething in children. Partial or general convulsions are very frequently due to either or both these causes. We have known the most violent opisthotonos co-existing for a considerable time with the presence of lumbricoid ascarides in the intestine; but ceasing immediately on the removal of the worms. Vomiting is commonly sympathetic of diseased kidney, or of the passage of a calculus along the ureter; or of the passage of a gall-stone along the gall duct; or it may be induced by the introduction of a catheter into the urethra.

The consentaneous action of symmetrical parts is no doubt due to a similar cause to that by which most of the sympathetic actions are excited, and more especially in those parts where symmetry of action is constant, although liable to be interrupted by the influence of the will.

A distinct class of sympathetic actions consists of those in which certain parts enlarge or become developed simultaneously with, and to a certain extent in effect of, the increase

* It has been remarked, that the term "sympathetic *actions*" involves a contradiction. But it may be observed, that the contraction of the muscles, on which the action depends, is only the natural mode in which that class of vital organs can manifest their consent with certain states of nervous centres, or of sensitive nerves. The action is the result of the state which the muscle assumes in sympathy with the stimulated nerve. The contradiction is therefore apparent, not real.

of others. The penis, the beard, the vocal organs, experience a marked increase of development at the adult period of life simultaneously with the enlargement of the testes; and, it may be added, in effect of their increase, because the early removal of these organs prevents the growth of the others. And so likewise as the ovaria are developed, the uterus, the vulva, the mammæ, increase in size; the ovarian and uterine irritation which accompanies the menstrual flux causes enlargement of the breasts, which subsides as soon as that period has gone by.

The various examples enumerated in the preceding paragraphs may be classed under three heads: first, sympathies between different individuals; secondly, those which affect the mind, and, through it, the body; and, thirdly, those which are strictly organic, and therefore physical.

Of the first class of sympathies we can offer no physical explanation. Whether the nervous system of one individual can directly affect that of another, or whether the effect is produced on the imagination, and afterwards on the nervous system, are questions still *sub judice*. The serpent fascinates his prey, apparently by the power of his eyes, and it is well known that one man can exert a marked control over another by a mere look; and in the same way man can control other animals, even the fiercest carnivora, by a firm and decided glance of the eyes. It is no explanation of sympathetic phenomena of this kind to ascribe them to the effect of a tendency to imitation. Imitation is voluntary; these actions are involuntary, or take place even in despite of the will.*

In the second class of sympathetic phenomena, an affection of the mind is a necessary link. But why that affection of the mind should produce its peculiar effect is a question difficult to solve. Why should the perception of certain odours produce in one case increased action of the salivary glands, and in the other case cause syncope? The only reply which can be made to this question is, that in these instances the impression on the sensorium causes a change there analogous to that which an original affection of the mind of similar kind would produce, and therefore gives rise to effects of the same nature as those resulting from that mental change. Thus the smell of savoury food excites in the mind the idea of food, which in a hungry man would, if it occurred spontaneously, occasion a flow of saliva. And the odour which occasions syncope, creates in the mind an emotion of disgust, which, if it arose independently of the physical impression, would affect the heart through the centre of emotion. It is plain, however, that that portion of the nervous centre which is affected in such cases, must have a direct influence upon the parts in which the sympathetic phenomena appear; and this through commissural fibres, or the continuity of its gray matter with that of the centre from which its nerves immediately spring; thus, in the instances referred to, the centre of sensation, which is first affected, is, through the medulla oblongata, connected with the salivary glands by the fifth nerve, and with the heart by the vagus.

We derive an explanation of the third class of sympathetic phenomena from the known laws of sensitive and motor nerves. It is known that stimulation of a sensitive nerve at its origin, or in any part of its course, will give rise to a sensation which will be referred to the peripheral extremity of the stimulated fibres; and that a stimulus applied to a motor nerve causes a change in it which spreads peripherad from the point stimulated, and therefore affects the muscular parts with which it is connected. It is known also, that a sentient nerve may excite a motor or sensitive nerve which is implanted near to it in the nervous centre — doubtless through the change which it produces in that centre; nor can it be doubted that a sensitive nerve may receive such a powerful stimulus as to exalt the polar force of a large portion of the nervous centre in the neighbourhood of its insertion, and thus to excite a similar change in all the nerves, whether motor or sensitive, which are connected with it. Thus, according to the intensity of the original stimulus, there will be a radiation of nervous force from the centre, either in one or two motor or sensitive nerves, or in several such; and the number and variety of the sympathetic phenomena will thus depend on the intensity and extent of the change in the nervous centre excited by the primary stimulus.

To explain, then, the phenomena of sensation and motion under consideration, we must determine the individual nerves affected in each instance, and ascertain what connexions they have with each other. We learn from anatomical investigation, that, although nerves anastomose with each other in their distribution, this anastomosis is by no means of that kind which would justify the supposition that an irritation could be communicated from one to the other in their course. The nerve-fibres only lie in juxtaposition, but do not communicate; and there is an evident provision in the tubular membrane and white substance of Schwann for the insulation of the central axis, which is probably the effective substance in the nervous action. We must seek, therefore, in the nervous centres for such a communication between these nerves as may explain the excitability of one by the other. In the present state of our knowledge we can do no more than state it as in the highest degree probable that nerves implanted in the centre immediately contiguous to each other can exert an influence upon the vesicular matter of the centre, and upon each other.

But there are certain facts which demonstrate beyond all doubt, that, in such actions as we refer to, the integrity of the centre forms a necessary condition. First, in many of the instances it is plain that there can be no connexion between the affected nerves elsewhere than in the centre, for they are so distinct from each other that there is not even

* Bostock's Physiology, vol. iii. p. 227.

that apparent connexion which results from the anastomosis of a fasciculus of fibres of the one with a portion of the other. Secondly, the removal of the portion of the nervous centre with which any one of the nerves concerned in the sympathetic action is connected, will prevent the development of the phenomenon, although the nerves themselves remain uninjured in their peripheral distribution, or in their connexion with each other. Thirdly, if there were any peripheral communication between nerves, it would be most likely to take place in the plexuses. Experiments, however, upon the nerves which lead to these show that each nerve-tube, in its passage through them, retains its isolation as distinctly as in any other part of its course. The three nerves which supply the lower extremity in the frog, says Müller, form a plexus from which two nervous trunks issue: if one of these latter be divided and isolated from all its connexions with muscles, and the portion of it connected with the plexus irritated, the impression will be transmitted in the centripetal direction by the sensitive fibres of nerve; but the motor fibres of the other nerve arising from the plexus are not affected, and excite no contractions in the muscles to which they are distributed.*

In applying these principles to the explanation of the instances which we have quoted, we shall find it difficult to determine the central connexion in some, although in others such a connexion is highly probable. It remains, therefore, for future anatomical research to ascertain what that connexion is which enables one nerve to sympathise with another. In the instance of pain in the shoulder in sympathy with irritation of the liver, the hepatic irritation excites a change in some sensitive nerves, which is propagated to the centre, and there affects some of the sentient fibres distributed in the region of the shoulder. The phrenic and the external thoracic nerves are both or either of them, but more especially the former, favourably situated to constitute the excitant of such a sympathetic sensation. The phrenic nerve of the right side is largely distributed upon the peritoneal surface of the diaphragm, and upon the inferior vena cava, and forms many connexions with the hepatic plexus in the substance of the liver. It may therefore readily participate in any irritation of that organ. Now, the phrenic nerve is implanted in the spinal cord on a level with the third or fourth cervical nerves; and the nerves of the shoulder form their connexion with this central organ about the same level. The origins of these nerves, therefore, are sufficiently contiguous to each other to warrant the belief that an irritated state of one may be propagated to the other through the vesicular matter of the centre. But it may be inquired why the irritation is limited to sensitive nerves of the shoulder; and why movements are not excited by the stimulation of the motor fibres of the phrenic itself, or of other nerves. The limitation of the irritation to one or two nerves depends on the degree of the stimulus, and the absence of any movements is due to the disposition of the phrenic nerve on the surface being unfavourable for the excitation of motions by irritation of its peripheral branches. And the experiment cited from Müller, in the last paragraph, shows that simple irritation of the *trunk* of a compound nerve in connexion with the centre is not sufficient to produce motion; which requires probably either a more prolonged and violent irritation of the nerve, or a polar state of the centre in which it is implanted.

* Baly's Müller, vol. i. p. 756.

Some of the instances of sympathetic sensations, referred to above, do not admit of an explanation so obvious. The pain over the brow from ice or cold water in the stomach may be referred to irritation of the gastric branches of the vagus, communicated in the medulla oblongata to the fifth; but why the irritation should be limited to the ophthalmic division of the fifth cannot be accounted for in the present state of our knowledge.

In those sympathetic movements which are of ordinary and normal occurrence, two provisions seem to be secured, namely, a certain peripheral organisation of the excitor nerve, and a certain central relation between it and the motor nerve. But in those which are of a morbid kind, it is necessary to suppose the existence of a more or less exalted polarity of the centre in order to explain the phenomena fully. This polar state will continue in many instances even after the primary peripheral irritation has been removed, as in tetanus, or in the convulsions from intestinal irritation; and we learn from this fact the importance in practice of attending to the state of the nervous centre, as well as to the removal of the irritating cause.

There are other sympathetic phenomena, of the physical kind, in which, however, the nervous system does not appear to take a prominent part. Such are the changes which occur in different and distant organs in connexion with a particular period of life, or the development of a particular function. Among these are the phenomena of puberty in both sexes; the enlargement of the mammæ in pregnancy. Whatever part the nervous system may take in such changes, it is impossible to account for them by reference to that system only; they must rather be regarded as phenomena of nutrition occurring in harmony with the laws of growth, and therefore affecting the vital fluid more particularly than any part of the system of solid parts.

Continuity of texture disposes, as is well known, to the extension of a diseased state originating at some one point. So also does *contiguity*. Phlegmonous inflammation of the areolar tissue, and erysipelas in the skin, spread with great rapidity. Inflammation arising in one of the opposed surfaces of a serous membrane readily attacks the other. These effects have been vaguely assigned to sympathy (the *continuous* and *contiguous* sympathy of Hunter). But it cannot be supposed that the nervous system takes part in the production of such phenomena, which ought rather to be ascribed, in the one case, to the continuity of blood-vessels, and, in the other, to contamination either by effused fluids or by morbid blood. (*R. B. Todd.*)

SYNOVIA is that fluid which exists within the membrane lining joints, to assist motion by lubrication; as also in the bursæ. The membranes generally, which line the various cavities of the body, are lubricated by fluid. This varies in character according to circumstances; and among these perhaps none more tend to the requirement of especial conditions than that of active and frequent motion, involving friction of the surfaces so lubricated.

Thus we find that the fluid of the pericardium differs essentially from that of the ventricles of the brain; while again the synovia, supplying moisture to the joints, varies greatly from the fluid of the pericardium, probably in order to assist the opposed surfaces in bearing friction in an exaggerated degree. The word attrition appears, indeed, the most appropriate to the conditions relieved by the presence of synovia, placed as it is between surfaces occasionally strongly approximated either by superincumbent weight or muscular contraction.

Synovia was chemically examined by Margueron.* The specimen he analysed was viscid, and became gelatinous soon after it was obtained. It then deposited a fibrous matter, and became clear above. Though the analysis of Margueron was not conducted on the more exact principles characterising those of the present day, it still serves to show that the specimen was peculiar as an animal fluid, and differed in one respect from the fluids generally, which lubricate surfaces. Thus it appears that as much as 11·86 per cent. was composed of fibrinous matter (fibrin), which coagulated, as stated before, soon after the fluid was obtained.

Margueron's analysis is as follows:—

Fibrin - - - - -	11·86
Albumen - - - - -	4·52
Chloride of Sodium - -	1·75
Soda - - - - -	0·71
Phosphate of Lime - -	0·70
Water - - - - -	80·46
	100·

Synovia has of late years been examined by John.† It is described as a viscid transparent yellowish or reddish fluid, resembling in its odour the serum of the blood. The analysis is stated as follows:—

Water - - - - - -	92·80
Albumen - - - - - -	6·40
Extractive Matter, Chloride of Sodium, and Carbonate of Soda - - - - - -	0·60
Phosphate of Lime - - -	0·15

It will be seen that these two analyses vary greatly — they were not made, it must be recollected, at the same date; and the methods of animal analysis are greatly improved since Margueron published. There is, however, an important point in which both analyses agree, viz. in stating phosphate of lime among the constituents of the fluid. John makes no mention of the existence of a coagulable fibrinous matter; a fact of much importance, which it appears desirable carefully to inquire into, insomuch as it is very possible the analyst may have extracted the synovia after coagulation had occurred within the membrane, and so obtained the clear fluid only; while Margueron may have been fortunate enough to secure it before such change had taken place, and in its natural condition.

With regard to this subject, on which our knowledge is but scanty, it appears still of importance to reflect on the material before us; and it is matter of no small interest to consider how far the results of peculiar mechanical conditions are modified by variations in the character of lubricating fluids, knowing, as we do, that, while the ventricles of the brain, subject to agitation only, contain no albumen in their lubricating fluid, the liquor of the pericardium contains that principle in abundance; and that in the synovial fluid adapted to the lubrication of the joints, we have, in addition to albumen, not only a considerable proportion of phosphate of lime, but probably fibrin also, as a necessary constituent. (*G. Owen Rees.*)

TASTE.—The sense by which we distinguish the *sapid* properties of bodies. The term, as commonly understood, includes much more than this; being usually employed to designate the whole of that knowledge of the qualities of a body (except such as is purely tactile), which we derive through the sensory apparatus situated within the mouth. But it will be hereafter shown that a considerable part of this is dependent upon the assistance of the *olfactive* sense; which is affected, through the posterior nares, by the odorous emanations of all such bodies as are capable of giving them off; and the indications of which are so combined with those of the true gustative sense, as to make an apparently single impression upon the sensorium. Moreover, there are certain sensorial impressions received through the organ of taste, which are so nearly allied in their character to those of *touch*, as to render it difficult to specify any fundamental difference between them: such are the *pungent* sensations produced by mustard, pepper, the essential oils, &c.; all of which substances produce a sensation when applied for a sufficient length of time to any part of the cutaneous surface, which can scarcely be distinguished from that excited through the organ of taste, in any other way than by its inferior intensity, and by the absence of the concurrent odorous emanations. The *taste* of such substances might, perhaps, be considered, therefore, as the composite re-

* Ann. de Chimie, xiv.

† Simon's Animal Chemistry. Trans. Sydenham Society.

sult of the impressions made upon the sensorium through a refined and acute *touch*, and by the effect of their odorous emanations upon the organ of *smell*. After making full allowance, however, for all such as can be thus accounted for, there remains a large class of pure *sapors*, of which we take cognizance without the assistance of smell, and which are altogether dissimilar to any tactile impressions: such are the bitter of quinine, the sour of tartaric acid, the sweet of sugar, the saline of common salt, &c. The smell can give us no assistance in distinguishing small particles of these bodies, since they are either entirely inodorous, or so nearly so as only to be recognizable through its means when in large masses; and the most refined touch cannot afford any indication of that kind of difference among them, of which we are at once rendered cognizant by taste. Still the gustative sensations scarcely differ more from the tactile than some of these last differ among each other,—the sense of heat and cold, for example, from the simple sense of contact or resistance; and we shall find that the analogy between these two senses is so strong, both as to the conditions under which they are respectively exercised, and the structure of the apparatus through which the impressions are received, that they must be regarded as much more nearly related to each other than either of them is to the other senses, or than the latter are amongst themselves.

The seat of the sense of taste is always at the entrance to the alimentary canal; and its purpose is obviously to afford a means of discrimination among the substances introduced into the mouth as food. The surface of the tongue is undoubtedly the special organ of taste in the higher animals; but there is adequate evidence that the sense is not entirely restricted to that organ, even in man; and it would seem improbable, considering the obvious purpose of the sense, that it should be wanting in that very large proportion of the animal kingdom in which no tongue exists, or in which the surface of that organ is so hard and horny as to forbid our attributing to it the possession of gustative sensibility. Without affirming (with Magendie) that the specific gustative sensibility extends over the teeth, the gums, the palate, and the pharynx, we feel justified in stating that in most persons it is distinctly present on the surface of the soft palate, especially in the neighbourhood of the uvula, and on that of the arches of the palate and of the fauces; and in a less degree on the surface of the anterior part of the soft palate. In making experiments upon this point, as well as upon many others connected with the sense of taste, it is important to bear in mind that if aromatic substances be employed, the impressions derived through the sense of smell may confuse the result; and also that if the sensory surface be too much exposed to cold air, its sensibility will be greatly diminished. Further, it should be borne in mind that a considerable amount of individual difference may not improbably exist, both as to the extent of the gustative surface, and the relative acuteness of the sense in different parts.

Conditions of the Sense of Taste.—In order that gustative impressions may be communicated to the sensorium, the first requisite is an afferent nerve, endowed with the power of receiving and transmitting them. The gustative surface in man and the higher animals being supplied by two afferent nerves,—the glosso-pharyngeal, and the lingual branch of the fifth pair,—we shall have to inquire whether both of these are subservient to the sense of taste, as well as to that of touch; or whether, as in the case of the organs of smell, sight, and hearing, there is one nerve of *special* and another of *general* sense. The peripheral extremities of both these nerves are in relation with a *papillary* apparatus, in which they are elevated above the general surface, and come into close proximity with capillary loops; and here, as elsewhere, it appears certain that the neighbourhood of circulating blood is an essential condition for the reception of sensory impressions. For the gustative nerve-fibres to be impressed by the distinctive properties of sapid substances, it would further seem requisite that these substances should be brought into immediate relation with them, and that they should penetrate, in the state of solution, through the investments of the papillæ, into their substance. This would seem to be proved by the two following facts: first, that every substance which possesses a distinct taste is more or less soluble in the fluids of the mouth, whilst substances which are perfectly insoluble do not make their presence known in any other way than through the sense of touch; and, second, that if the most sapid substance be applied in a dry state to the papillary surface, and this be also dry, no sensation of taste is excited. Hence it may be inferred that, in the reception of gustative impressions, a change is produced in the molecular condition of the nerve-fibres, or, to use the language of Messrs. Todd and Bowman, their polarity is excited, by the direct agency of the sapid matter itself. This change may be induced, however, both by electrical and mechanical stimulation. If we make the tongue form part of a galvanic circuit, a peculiar sensation is excited, which is certainly allied rather to the gustative than to the tactile, and which does not seem to be due (as at one time supposed) to the decomposition of the salts of the saliva. And, as Dr. Baly has pointed out*, "if the end of the finger be made to strike quickly, but lightly, the surface of the tongue at its tip, or its edge near the tip, so as to affect not the substance of the organ, but merely the papillæ, a taste sometimes acid, sometimes saline, like the taste produced by electricity, will be distinctly perceived. The sensation of taste thus induced will sometimes continue several seconds after the application of the mechanical stimulus."

* Translation of Müller's Physiology, p. 1062, *note*.

On the other hand, as Wagner has truly remarked, if the surface of the tongue near the root be touched with a clean dry glass rod, or a drop of distilled water be placed upon it, a slightly bitterish sensation is produced; and this, if the pressure be continued, passes into that of nausea, and if the pressure be increased even excites vomiting. The feeling of nausea may be excited by mechanical irritation of any part of the surface of the fauces and soft palate; and this feeling is certainly much more allied to that of taste than to that of touch. Further, it has been observed by Henle, that if a small current of air be directed upon the tongue, it gives rise to a cool saline taste like that of saltpetre. Thus we find that the peculiar effects of sapid substances upon the nerves of taste may be imitated to a certain extent by other agencies; and it also appears that the sensations excited by these vary according to the part of the gustative surface on which they operate; mechanical or electrical stimulation of the front of the tongue giving rise to a kind of saline taste, whilst mechanical stimulation applied to the back of the tongue and fauces excites the feelings of bitterness and nausea.

One of the conditions requisite for the due exercise of the gustative sense, is a temperature not departing far on either side from that which is natural to the body. It appears from the recent experiments of Prof. E. H. Weber *, that if the tongue be kept immersed for nearly a minute in water of about 125°, the taste of sugar brought in contact with it, either in powder or solution, is no longer perceived; the sense of touch, usually so delicate at the tip of the tongue, being also rendered imperfect. A similar imperfection of taste and touch was produced by immersing the tongue for the same length of time in a mixture of water and broken ice.

Nerves of Taste.—Much controversy has taken place upon the question whether or not there be a special nerve of taste; and whether the lingual branch of the fifth pair, or the glosso-pharyngeal, possesses the best claim to this title. The principal points of this controversy have been already noticed [See FIFTH PAIR and GLOSSO-PHARYNGEAL]; a short review of it, however, with a notice of the most recent inquiries on the subject, will be here desirable. That the *glosso-pharyngeal* is the special nerve of taste, and that its complete section on both sides destroys the sensibility to gustative impressions, was first affirmed by Panizza; and his conclusions, adopted by Dr. M. Hall and Mr. Broughton †, have been since, to a certain extent, supported by the experiments of Valentin ‡ and Bruns.§ The grounds on which this doctrine rests are briefly as follows:—After recovering from the depression which is the immediate consequence of the operation, a dog whose glosso-pharyngeal nerves have been divided is said to eat pieces of meat rendered bitter with colocynth, and to drink milk and water dosed with the same drug, without any repugnance; whereas if the lingual nerves be divided and the glosso-pharyngeals left entire, the bitter morsel is rejected as soon as it reaches the back of the mouth, although it may have been at first seized very hastily. But, on the contrary, it has been affirmed by Kornfeld *, with whom Müller and Gurlt were associated, by Dr. Alcock †, by Dr. John Reid ‡, by Guyot and Cazalis §, by Magendie ||, by Longet ¶, and by Volkmann and Bidder **, that distinct indications may be obtained of the persistence of the sense of taste, after complete section of the glosso-pharyngeal nerves on both sides. Of a dog in which the nerve had been divided before giving off a single filament, Dr. J. Reid states:—"I have repeatedly fed that dog with morsels of animal food from my hand; and after he had taken several morsels in this way, which he readily swallowed, I then presented a morsel similar in size to the others, and with the colocynth, concealed in a way that he could not see it; but no sooner was it taken into the mouth than it was rejected with evident symptoms of disgust. This was repeated more than once." Bidder found that although two dogs whose glosso-pharyngei had been divided, swallowed pieces of flesh soaked in an infusion of colocynth, which another dog whose nerves were uninjured at once rejected, yet certain movements of the lips and tongue were observed, which showed that these were not altogether relished. It is obvious that, in such an inquiry, positive evidence of the continuance of the sense of taste is more conclusive than the negative evidence from which its absence may be inferred. It is right to bear in mind that, as Wagner has pointed out, dogs when they are hungry will devour meat however strongly seasoned with bitter drugs, though all their nerves be entire. Dr. Reid makes the remark, in explanation of the results of Panizza, that one of the dogs on which he had divided the glosso-pharyngeal nerves, would eat the morsel of meat containing colocynth, rather than lose it, when very hungry; though he refused it, if he saw any prospect of procuring another free from the bitter. Wherever any such evidence of the persistence of the sense of taste was obtained, this appeared specially to exist in the *anterior* portion of the mouth.

** Articles *Nervenphysiologie* and *Schmecken* in Wagner's Handwörterbuch der Physiologie.

On the other hand, it has been maintained by some physiologists (especially Magendie, Müller, Gurlt, and Kornfeld), that the *lingual branch of the fifth pair* is the special nerve of taste ; although Müller does not altogether exclude the participation of the glosso-pharyngeal as having a share in the transmission of gustative impressions from the posterior part of the tongue and the fauces. The experiments of Dr. Alcock and others, however, appear to show that very distinct indications of gustative sensibility are presented by animals in which this nerve has been divided, the sense being merely deficient in the anterior part of the tongue.

On the whole, then, it may be concluded from experiment, that the glosso-pharyngeal nerve and the lingual branch of the fifth pair minister alike to the sense of taste; the former being concerned in the transmission of gustative impressions from the fauces and the posterior part of the tongue, and the latter from the anterior portion of the tongue ; and the former being the special recipient of the impressions which produce the sense of nausea. This inference is so completely in harmony with the results of anatomical inquiry, that it may be considered as having a very strong claim to reception as a physiological truth. The branches of the glosso-pharyngeal appear to constitute the sole nervous supply of that region at the base of the tongue, of which the circumvallate papillæ form the centre, and also of the sides of the tongue near the base. As it is universally admitted that these parts are acutely endowed with gustative sensibility, we cannot help regarding the glosso-pharyngeal nerve as its instrument. On the other hand, the middle and anterior parts of the dorsum of the tongue appear to be solely supplied from the fifth pair, —the tip, however, receiving a branch from the glosso-pharyngeal, which runs towards it, along the under surface. It has been denied by some physiologists that the central portion of the upper surface possesses the proper gustative sensibility; but we fully coincide in the statements of those who maintain the affirmative: and although it must be admitted that the sense is not so acute as it is at the base, sides, and apex of the tongue ; yet this may be fairly attributed to the greater thickness of the epithelial investment, and to the predominance of the conical papillæ over the fungiform in the central region.

On turning to the pathological evidence which bears upon this question, we find an apparent contradiction in the phenomena recorded by different observers; but this is in a great degree removed by a more careful examination; and the evidence on the whole preponderates in favour of the preceding conclusions. We shall make use of the excellent summary recently put forth by Dr. J. Reid * : —"In the single cases observed and recorded by Mayo, Serres, Romberg, Mr. Bishop, and Todd and Bowman, and in the two cases by Mr. Dixon, both common sensation and the sense of taste were annihilated in those parts of the tongue supplied by the fifth pair ; while in one case related by Mr. Noble, and another by Vogt, common sensation was lost in the parts of the tongue supplied by the third branch of the fifth pair, yet the sense of taste remained in these parts; and in a second case related by Mr. Noble, there was loss of taste with maintenance of feeling." In some of these cases the loss of the sense of taste appeared to extend to the base of the tongue; but there was evidence that in these the glosso-pharyngeal nerve was also involved in the paralysis. "We have no proof," continues Dr. Reid, "that in the cases related by Mr. Noble and Vogt, *the whole* of the filaments of the fifth pair sent to the tongue were affected; and in the case of Vogt the derangement of the nerve was only temporary, for the patient recovered the sensation of the part paralysed after the end of six weeks. We believe that these cases, when examined more closely, will rather be regarded as affording arguments in favour of the opinion, that the same nervous filaments do not convey inwards the impressions which excite pain and touch and the impressions which excite taste ; and that different filaments for conveying inwards the impressions that excite these sensations are bound up in the lingual branch of the fifth pair." There is believed to be no case on record, in which the whole of the fifth pair, or of the third branch of it, was found to be diseased after death, and in which, during life, the sense of taste had been retained in the anterior and middle parts of the tongue. The evidence of pathology, therefore, is in favour of that conclusion, as to the participation of the fifth pair with the glosso-pharyngeal in the sense of taste, at which we had arrived on other grounds.

The question still remains, however, as to the *speciality* of the nervous fibres which convey the gustative impressions ; that is, whether they are the common sensory fibres, whose peculiarity of function depends on the nature of the papillary apparatus at their peripheral origin; or whether they are incapable, like the fibres of the olfactive, optic, and auditory nerves, of conveying impressions of the ordinary sensorial kind, being adapted exclusively to receive and transmit the peculiar impressions made by sapid bodies. Now, in favour of the first view, it may be urged, that the conditions of the sense of taste are so nearly allied to those required for the exercise of touch, that the two can scarcely be distinguished on this ground, and that the fifth pair and the glosso-pharyngeal are both nerves of common as well as of gustative sensibility ; neither of which can be affirmed in regard to the three other senses, or of the nerves which minister to them. But, on the other hand, it must be remarked, that these nerves do not seem to be endowed with gustative and common sensibility in equal proportions; for the glosso-pharyngeal, which is decidedly more

* Physiological, Pathological, and Anatomical Researches, p. 268.

susceptible than the lingual to gustative impressions, far less readily excites manifestations of pain when subjected to mechanical irritation. Hence, it would seem not improbable, that there may be in each a mixture of the fibres which minister to the sense of taste with those of tactile sensibility; and that the former may be so far special in their endowments, as to be capable of receiving only the peculiar impressions made by sapid bodies, to which the latter may be insensible. Such a view would seem to be supported by the cases of Vogt and Noble just referred to; and it is in harmony with the views to which we are led from the consideration of the diversities manifested between the sense of heat and cold and that of simple contact. [See Touch.]

Gustative Papillæ.—The tongue is copiously furnished with a papillary structure, bearing a close resemblance to that of the skin, but in many respects more complicated. Referring to the article Tongue for a more particular anatomical description of these papillæ, we have now to inquire into their connexion with the sense of taste. According to the recent investigations of Messrs. Todd and Bowman, the lingual papillæ are either *simple* or *compound;* the former, which do not differ from those of the cutaneous surface in any other obvious character than the nature of their epithelial investment, are scattered over the whole surface of the tongue, in parts where the others do not exist, but they also participate in the formation of the compound papillæ; the latter are of three kinds, the *circumvallate* or *calyciform*, the *fungiform*, and the *conical.*—The *circumvallate* papillæ, which are only eight or ten in number, and are restricted to a small space at the base of the tongue, consist merely of groups of simple papillæ, arranged in a peculiar manner, and separated from those of the adjacent mucous membrane by a circular fissure. Into these simple papillæ it has not yet been found possible to trace any distinct nerve-fibres, though there can be little doubt that it is penetrated by at least the essential part of them.—The *fungiform* papillæ are scattered singly over the surface, chiefly about the sides and apex, and but very sparingly in the middle of the dorsal region, though they are abundant in front of the circumvallate papillæ. These are composed of aggregations of simple papillæ, which rise, however, considerably above the surface, and are covered with an epithelium so thin that they are distinguished by their blood-red colour. Fasciculi of nerve-tubes may be distinctly traced into them; but of the nature of their termination it would be unwise to give a positive statement. Some of the appearances presented by them favour the idea that they form loops at their peripheral extremities; whilst, in other instances, the tubular portion of the fibre, with the white substance of Schwann, seems to terminate somewhat abruptly, whilst the central axis is continued onwards into the substance of the enveloping tissue, in which it loses itself. —The *conical* or *filiform*, which are the most numerous of the compound papillæ, are diffused over the whole surface of the tongue, though most largely and numerously developed in its central part. They consist of clusters of simple papillæ of a peculiarly elongated form, containing tubular nerve-fibres, which may frequently be seen to form distinct loops in their interior; but their chief peculiarity consists in their epithelial investment, which forms about two-thirds of their length, and gives to them their whitish tint. This investment consists of a tuft of long pointed processes, some of which present a near approach in their dense texture to hair; whilst others may be regarded as soft or uncondensed hairs. These processes are sent off from the sides and summits of the secondary papillæ, and are usually inclined backwards, lying buried in the recesses of the mouth. The foregoing description applies, however, only to the conical papillæ of the human tongue; and there is a considerable diversity in their structure in other animals. Thus, in the Ruminants, each conical papilla is terminated by a long, slender, flexible, horny filament, curving backwards; and in the Felines some of them are furnished with a brush-like tuft of slender horny filaments, like those of man*, whilst others are encased by firm horny sheaths, which are prolonged backwards as stiff spines. It is to this arrangement that the peculiar roughness of the tongue of the cat is due; the organ being thus enabled to act as a flexible rasp, whereby the bones which they lick may be effectually cleaned of the smallest particles of flesh that may adhere to them; and a single stroke of the tongue of a lion is said to be capable of abrading the whole thickness of the human skin.

After what has been already said of the conditions essential to the exercise of the sense of taste, there is no occasion to do more than point out the evident fact, that, if some of the papillæ be covered with an epithelial investment so dense as to resemble horn, and offering an effectual barrier to the penetration of fluids, these cannot be supposed to have much participation in the sense, if they possess any. It is obvious that in the Felines the function of the spiny papillæ must be purely mechanical; and it seems probable that the brush-like papillæ which lie among them, in common with those of man, possess simple tactile sensibility, serving to direct those muscular actions of the organ, which so remarkably adapt it to deal with minute particles of food. On the other hand, the thinness of the epithelial investment on the simple papillæ which are scattered over the surface of the tongue, and which form the circumvallate and fungiform papillæ by their aggregation, indicates their special adaptation to receive gustative impressions; and this must be admitted to be more especially the case with the fungiform papillæ, which often

* By Cuvier these filaments are supposed to be the ultimate fasciculi of the fibres of the gustative nerve; but this is certainly an error.

undergo a kind of erection when sapid substances are brought into contact with them. This inference is in complete harmony with the relative acuteness of the senses of taste and touch, in the portions of the surface on which the one or the other class of papillæ is most abundant; thus the sides and back part of the tongue are unquestionably the parts where the gustative sensibility is the greatest, and it is there that the fungiform, circumvallate, and simple papillæ are most thickly set; whilst the apex and central part of the dorsum, over which the tactile sensibility is predominant, is that on which we meet with the largest number of filiform papillæ. Whether there be any difference among the simple isolated papillæ, and among those which are aggregated into the composite bodies that are termed fungiform and circumvallate, we are scarcely in a condition even to form a guess, until it shall have been determined whether the gustative and tactile nerve-fibres are identical or diverse in their endowments. If the former, it will be reasonable to suppose that every papilla through which a gustative impression can be made in virtue of the penetration of sapid matter into its tissue, may also be subservient to the reception of tactile impressions from mechanical stimulation. On the other hand, if it should be proved that the gustative sense depends on a *special* set of fibres, we should still have to inquire whether the same papilla may not contain fibres of both classes, so as to minister to both functions ; or whether some of the papillæ are purely gustative, whilst others are purely tactile.

At present there is no adequate reason to suppose that there is any essential difference of function among the papillæ covered with a soft thin epithelium, whether these be solitary or aggregate. An attempt was made by Horn * to establish some such diversity ; but the results of his experiments would rather lead to the supposition that there is a difference in the gustative sensations excited by the same substance, according as it is applied to different regions of the tongue, than to different papillæ. Thus he found that more than three-fourths of the substances which he applied to the circumvallate papillæ excited a bitter taste, or one in which a bitter was associated with some other flavour, especially an alkaline or saline ; whilst the majority of the substances applied to the filiform papillæ tasted acid, or acid with a mixture of bitter and sweet. But since, as we have seen, mere mechanical stimulation produces different gustative sensations according to the part of the tongue to which it is applied, it is probable that the difference in Horn's results is not to be set down to the account of the papillæ, but rather to that of the nerves by which they are respectively supplied.

Exercise of the Sense.—The simple application of a sapid substance to the gustative surface is usually sufficient to excite the sensation ; and if this application be restricted to one particular spot, we are able to recognise its place more or less distinctly. In this respect, then, the gustative impression resembles the tactile ; for whilst we cannot, by our own consciousness, distinguish the parts of the retina or of the auditory apparatus on which visual or auditory impressions are made, we can make this distinction in regard to the surface which is supplied by the nerves of general sense. This determination is most precise when the impression is made on the parts of the tongue of which the gustative sensibility is most acute ; namely, the apex, sides, and posterior part of the dorsum; being probably aided, however, near the tip, by the acuteness of its tactile sensibility. The impressibility of the middle portion of the dorsum is greatly inferior ; but still, when the gustative sensation has been excited there, it is referred to the spot on which the sapid substance was laid. The contact of sapid substances much more readily excites a gustative sensation, when it is made to press upon the papillæ, or to move over them. Thus there are some substances whose taste is not perceived when they are simply applied to the central part of the dorsum of the tongue, but of whose presence we are at once rendered cognizant by pressing the tongue against the roof of the mouth. The full flavour of a sapid substance, again, is more readily perceived when it is rubbed on any part of the tongue, than when it is simply brought in contact with it or pressed against it. Even when liquids are taken into the mouth, their taste is most completely discriminated by causing them to move over the gustative surface: thus the "wine-taster" takes a small quantity of the liquor into his mouth, carries it rapidly over every part of its lining membrane, and then ejects it. It is not improbable that this exaltation of the usual effects is simply due to mechanica causes ; the sapid particles being brought by the pressure or movement into more rapid and complete operation on the nerve-fibres, than they would be if simply placed in contact with the papillæ.

As in the case of the other senses, so do we find with regard to that of taste, that continual attention to its indications greatly increases its acuteness. Thus the "tasters" of wine, tea, &c., acquire a power of discrimination which is truly wonderful to those who have not exercised themselves in the same manner. Thus we have been informed that the "taster" to one of the extensive cellars of sherry wines at Cadiz or Seville has not the least difficulty in distinguishing the butt from which a given sample may have been drawn, although the number of different varieties of the same kind of wine under his keeping may not be less than five hundred. So we are informed by Dr. Kitchener that many London epicures are capable of saying in what precise reach of the Thames the salmon on the table has been caught; and the Parisian *gourmet* is said to be able to distin-

* Ueber den Geschmacksinn des Menschen. Heidelberg, 1825.

guish by the taste, whether the birds on which he is dining are domesticated or wild, male or female, or to give an exact determination of the spices, &c., that are combined in a particular sauce.

On the other hand, the power of distinguishing sapors is for a time suspended, when several substances of very decided but different tastes are taken into the mouth in quick succession: thus, if sweet, sour, salt, or bitter substances be applied to the tongue, or if different kinds of wine be taken, one after another, the sense is so much blunted after a short time, as to impair or destroy the power of discrimination between them until after an interval of rest. So, again, when two substances of very different flavours are mingled together, the stronger will frequently mask the presence of the weaker: thus we often find it advantageous, in prescribing nauseous medicines, to combine with them aromatics, whose stronger impression shall take possession (so to speak) of the sense for a time; and the object may be still more completely attained by giving the aromatic a moment or two previously, instead of simultaneously with the disagreeable substance.

The influence of habit in blunting the sensibility to particular tastes, is as remarkable as it is in the case of other sensations. Still more extraordinary, however, is the degree in which the taste may be educated to approve savours which are in the first instance most disgusting. "Thus," says Dr. Dunglison*, "the Roman *liquamen* or *garum*, the most celebrated sauce of antiquity, was prepared from the half-putrid intestines of fish: and one of the varieties of the Οπος σιλφιου, or *laserpitium*, is supposed to have been the assafœtida. Even at this time, certain of the Orientals are fond of the flavour of this nauseous substance. Putrid meat is the delight of some nations; and a rotten egg, especially if accompanied with the chick, is highly esteemed by the Siamese. In civilised countries, we find game, in a putrescent state, eaten as a luxury; this, to those unaccustomed to it, requires a true education. The same may be said of the pickled olive, and of several cheeses; the *fromage de Gruyère*, for example, so much esteemed by the inhabitants of continental Europe." Very extraordinary appetencies for particular flavours are sometimes morbidly developed; as in the case of chlorotic girls, pregnant women, and insane patients. The latter will sometimes even devour their own excrement.

Independently of the changes produced by the education of the taste, we find great alterations in the likes and dislikes connected with it, taking place in accordance with the development of the body, or with other changes in its physiological conditions. Thus to the infant there is obviously nothing so agreeable as milk; in more advanced childhood there is almost invariably a fondness for sweets; whilst after adult age this is usually in a great degree superseded by a preference for other savours. It sometimes happens that articles of diet which were peculiarly agreeable to us in childhood, become positively disgusting to us in later life; whilst, on the contrary, many things to which we feel a strong distaste in childhood, are relished when we come to be men, and this by a spontaneous change in our own appetencies. We fully believe with Wagner that these alterations are in some way connected with the physical condition of the nutritive functions; for we have other examples in which this connexion is very evident. Thus, we may continually remark that articles of food for which we have the keenest relish when we commence a meal with a good appetite, become positively distasteful when we have already satisfied it. Again, we have known persons who have a positive repugnance to fatty or oleaginous matters of almost any description, so long as they reside in temperate climates, but who eat them with avidity when exposed to the severe cold of the arctic winter. And even in our own country we may frequently remark that the taste for such articles varies with the temperature; a cup of sweet oleaginous cocoa, which would be almost loathed on a hot summer day, being very palatable on a cold winter night; whilst ascescent drinks, such as would be greatly relished in the former season, are altogether discarded in the latter, except when a heated atmosphere brings back the physical condition of the system which renders them palatable.

So, again, we often observe in illness that an alteration in the physical conditions of the system so far affects the sense of taste, as to produce a great alteration in the usual appetencies. These alterations may probably be due in some instances to the depravation of the buccal secretions, so that the gustative papillæ are constantly surrounded with a substance possessing a certain taste of its own, which of course affects their impressibility by other savours. But there can be little doubt that they are more commonly occasioned by alterations in the condition of the gustative apparatus itself, which becomes the exponent (so to speak) of the wants of the system, and which may be trusted, to a very considerable extent, as indicating what is really most desirable for it. Thus Dr. Holland remarks*: — "In the majority of instances of actual illness, provided the real feelings of the patient can be safely ascertained, his desires as to food and drink may be safely complied with. But undoubtedly much care is needful that we be not deceived as to the state of the appetites by what is merely habit or wrong impression on the part of the patient, or the effect of the solicitation of others. This class of sensations is more nurtured out of the course of nature than are those which relate to the temperature of the body. The mind becomes much more deeply engaged with them; and though in acute illness they are generally submitted again to the natural law, there are many lesser cases where

* Human Physiology, vol. i. p. 116.

* Medical Notes and Reflections, p. 85.

enough remains of the leaven of habit to render every precaution needful. With such precautions, however, which every physician who can take schooling from experience will employ, the stomach of the patient becomes a valuable guide; whether it dictate abstinence from a recurrence to food; whether much or little in quantity; whether what is solid or liquid; whether much drink or little; whether things warm or cold; whether sweet, acid, or saline; whether bland or stimulating to the taste." Further, Dr. Holland remarks: "It is not wholly paradoxical to say that we are authorised to give greatest heed to the stomach when it suggests some seeming extravagance of diet. It may be that this is a mere depravation of the sense of taste; but frequently it expresses an actual need of the stomach either in aid of its own functions or indirectly (under the mysterious law just referred to) for the effecting of changes in the whole mass of blood. It is a good practical rule in such cases to withhold assent till we find after a certain lapse of time that the same desire continues or strongly recurs; in which case it may generally be taken as the index of the fitness of the thing desired for the actual state of the organs. In the early stage of recovery from long gastric fevers, I recollect many curious instances of such contrariety to all rule being acquiesced in, with manifest good to the patient. Dietetics must become a much more exact branch of knowledge, before we can be justified in opposing its maxims to the natural and repeated suggestions of the stomach, in the state either of health or disease." In regard to the use of wine in fever, it is universally admitted by practical physicians that very important indications may frequently be drawn from the appetency or dislike manifested towards it by the patient; this being often exhibited when there is an almost entire obtuseness of the mind in regard to all other external impressions. In such circumstances these dormant instincts seem to manifest themselves, which are kept under by the intelligence in the normal condition; instincts akin to those which guide the lower animals in their choice of food. There is probably not a plant, however poisonous to most, which has not one or more species of animal specially adapted to derive from it wholesome nutriment, and which is obviously drawn to it by its odour or savour; whilst the most omnivorous feeders, such as the monkey, are usually restrained by dislikes, excited through these same senses, from touching fruits which would be noxious to them.

It cannot be doubted that, in all persons of ordinary aptitude for the discrimination of flavours, there are certain natural harmonies and discords among these, as among colours and sounds; so that particular substances of very different flavours taste agreeably in combination, whilst others are mutually repugnant. Thus every body likes sugar in combination with the acid of fruits; and the sugar is popularly believed to neutralise the acid, which (as we need scarcely say) is not at all the case. On the other hand, sugar and oysters are said to form one of the most nauseous combinations possible. So, again, the flavour of many wines is improved by being tasted simultaneously with cheese, whilst it is injured by fruits.—The art of cookery is founded upon a knowledge of these facts, which have not yet perhaps received from the scientific physiologist the systematic attention they deserve. Attempts have been made by Linnæus, Boerhaave, and others, to form a classification of savours; but no such classification has come into general use, although there are certain savours which all agree to consider *primary;* such as the *aromatic*, the *sweet*, the *acid*, the *bitter*, the *saline*, the *astringent*, and the *pungent*. By the first of these the sense of taste is connected with that of smell; by the last two with that of touch.

The impressions made upon the sense of taste seem to remain longer after the withdrawal of the body that excited them, than those which are received through most of our other senses. This is not surprising, when it is considered that particles of the sapid substance, which have once penetrated the papillæ, may linger there in contact with the sentient extremities of the nerves, for some little time after they have passed away from the external surface. In many cases, however, the substance leaves an *after-taste* which is different from that which it first excited. It is difficult to say how much of this may be due to the difference of the impression which is made upon the sensory papillæ at the front of the tongue and upon those at its base, and also to the admixture of the olfactive sense, which will be most actively called into play as the sapid body is passing the fauces; and how much to the exhaustion of the nerves consequent upon their previous stimulation, so that the after-taste is *complementary* to that first received. It certainly appears to confirm the former explanation, that the after-taste is generally of that bitterish character which we have seen to be produced by the mere mechanical stimulation of the papillæ at the base of the tongue. On the other hand, the fact that *tannin*, one of the bitterest substances known, has a sweetish after-taste, seems to favour the latter view. Probably both causes may participate in the production of the result.

It is not very common to find the sense of taste excited in a purely *subjective* manner; since many of the tastes which are experienced in disease are probably due, as already remarked, to the depravation of the buccal secretions. Nevertheless, we occasionally meet with instances in which some peculiar gustative sensation, usually of a disagreeable nature, is constantly experienced without being traceable to any such cause; and in which, therefore, we must seek for its occasion in some disordered functional condition of the sensorium.

The *purpose* of the sense of taste is obviously to serve as the guide and attraction towards wholesome food, and to afford pleasure in the reception of it, whilst it deters from the use of such as would be deleterious. This is more obvious in the lower animals than it is in man, who is frequently led by habit and fashion to a preference for substances which are high-flavoured over those which are most wholesome, and who is still more frequently induced to gratify his gustative sense by the reception of an amount of food which appetite alone would not incite him to take in. Of the pernicious results of such excess, this is not the place to speak.

The only ulterior purposes which the sense of taste appears to perform in the economy, are to aid in exciting the flow of saliva, and in certain cases to excite the act of vomiting. Although the secretion of saliva is greatly affected by other causes,—as, for example, by the movement of the jaws, tongue, &c.,—yet it is much influenced by the sapid qualities of the food introduced into the mouth, being greatly increased by the taste of savoury food. It is also augmented by the sight or odour of such food; but it is probable that the latter sensations influence it not so much directly as indirectly, namely, through the *ideas* which they call up, for the idea alone, if called up with sufficient vividness, is sufficient to make "the mouth water." The sense of nausea, as already remarked, seems intermediate between taste and touch; but it is connected most closely with the former. We experience more or less of difficulty in swallowing all substances whose taste is peculiarly repugnant to us, and we find ourselves compelled to regurgitate them when the impression becomes of a certain intensity. This is one of the automatic actions in which it appears requisite that a *sensation*, not a mere impression, should participate.

(*William B. Carpenter.*)

TEETH.—Comparative Anatomy. (Sing. *a tooth; Tunth,* Teut.; *Dens,* Lat.; *Dente,* Ital.; *Dent,* Fr.; *Tand,* Dan.; *Tain,* Old English; *Zahn,* Germ.; *Dant,* Welsh; *Dend,* Erse; οδους-οδοντος, Gr.; *Dantis,* Lithuanic; *Dantas,* Sanscrit.*) A tooth is a hard body attached to the mouth or commencement of the alimentary canal, always exposed, save where its development is permanently arrested, as in the rudimental tusk of the Narwhal; commonly calcified, the exceptions being few, *e. g.,* the horny teeth of the Lamprey and Platypus. Teeth vary not only in their tissue, but still more in number, size, form, structure, position, and mode of attachment, in different animals: they are principally adapted for seizing, tearing, dividing, pounding, or grinding the food; in some they are modified to serve as weapons of offence and defence; in others as aids in locomotion, means of anchorage, instruments for uprooting or cutting down trees, or for transport and working of building materials; they are characteristic of age and sex; and in man they have secondary relations subservient to beauty and to speech.

Teeth are always most intimately related to the food and habits of the animal, and are therefore highly interesting to the physiologist: they form for the same reason most important guides to the naturalist in the classification of animals; and their value, as zoological characters, is enhanced by the facility with which, from their position, they can be examined in living or recent animals; whilst the durability of their tissues renders them not less available to the palæontologist in the determination of the nature and affinities of extinct species, of whose organisation they are often the sole remains discoverable in the deposits of former periods of the earth's history.

Although there are many analogous structures in the inverterbrate classes, true calcified teeth are peculiar to the Vertebrata, and may be defined as bodies primarily, if not permanently, distinct from the skeleton, consisting of a cellular and tubular basis of animal matter containing earthy particles, a fluid, and a vascular pulp.

In general, the earth is present in such quantity as to render the tooth harder than bone, in which case the animal basis is gelatinous, as in other hard parts where a great proportion of earth is combined with animal matter. In a very few instances among the vertebrate animals, the hardening material exists in a much smaller proportion, and the animal basis is albuminous; the teeth here agree, in both chemical and physical qualities, with horn.

True teeth consist commonly of two or more tissues, characterised by the proportions of their earthy and animal constituents, and by the size, form, and direction of the cavities in the animal basis which contain the earth, the fluid, or the vascular pulp.

The tissue which forms the body of the tooth is called "dentine," (*Dentinum,* Lat.; *Zahnbein, Zahnsubstanz,* Germ.; *l'Ivoire**, Fr.)

The tissue which forms the outer crust of the tooth is called "cement" (*cæmentum, crusta petrosa,* Lat.).

* These synonyms are cited as illustrative of the coincidence in one of the primary words of a natural class of languages that prevails from the East Indies, through the west of Asia and across Europe, and as indicative of the unity of stock of the great Indo-European family of mankind.

* The learned author of the article "Sécrétions," in the "Dictionnaire Universel d'Histoire Naturelle," 8vo, 1848, adopts the term "Dentine" in preference to Cuvier's name "ivoire," and after defining its properties, observes, "Sur ces divers rapports, le mot *dentine,* par lequel M. R. Owen les désigne, me paraît très heureux." The term "ivory" unavoidably recalls the idea of the peculiar modification of "dentine," which characterises the tusks of the elephant, mammoth, and mastodon; but, besides this objection to its more general application, the word is used in a still wider sense in the "Leçons d'Anatomie Comparée:" "Les unes (dents), en effet, ont la partie enfoncée dans l'alvéole dénuée d'émail; cette partie, ou la racine, ne se compose généralement que de l'*ivoire* intérieure, recouvert très rarement d'*ivoire* extérieure (les dents de cachalot);" tom. iv. Ed. posth. 1836, p. 200. The example cited of the tissue here denominated "ivoire extérieure" is the "cement." See my "Odontography," p. 355, pl. 89.

The third tissue, when present, is situated between the dentine and cement, and is called "enamel" (*encaustum*, *adamas*, Lat.).

"*Dentine*" consists of an organised animal basis disposed in the form of extremely minute tubes and cells, and of earthy particles: these particles have a twofold arrangement, being either blended with the animal matter of the interspaces and parietes of the tubes and cells, or contained in a minutely granular state in their cavities. The density of the dentine arises principally from the proportion of earth in the first of these states of combination, the tubes and cells contain, besides the granular earth, a colourless fluid, probably transuded "plasma" or "liquor sanguinis," and thus relate not only to the mechanical conditions of the tooth, but to the vitality and nutrition of the dentine.

This typical structure of dentine is well illustrated in the article Tooth: such "true dentine" has no canals large enough to admit capillary vessels with the red particles of blood, and it has been therefore called "unvascular dentine."

The simplest modification of dentine is that in which capillary tracts of the primitive vascular pulp remain uncalcified, and permanently carry red blood into the substance of the tissue. These so-called "medullary canals" or "vascular canals" present various dispositions in the dentine which they modify, and which I have proposed to call "vaso-dentine." It is often combined with true dentine in the same tooth; *e.g.* in the scalpriform incisors of certain Rodents*, the tusks of the Elephant†, the molars of the extinct Iguanodon.‡

A third modification of the fundamental tissue of the tooth is where the cellular basis of the dentine is arranged in concentric layers around the vascular canals, and contains "radiated cells" like those of the osseous tissue: it is called "osteo-dentine." The transition from dentine to vaso-dentine, and from this to osteo-dentine, is gradual, and the resemblance of osteo-dentine to true bone is very close.

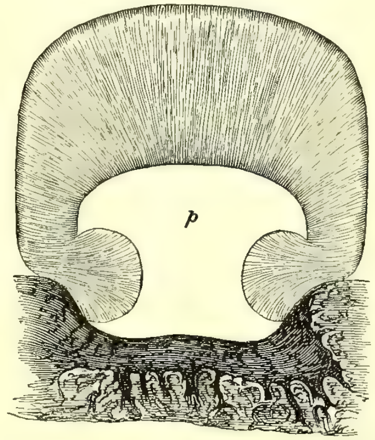
"*Cement*" always closely corresponds in texture with the osseous tissue of the same animal; and wherever it occurs of sufficient thickness, as upon the teeth of the horse, sloth, or ruminant, it is also traversed, like bone, by vascular canals. In reptiles and mammals, in which the animal basis of the bones of the skeleton is excavated by minute radiated cells, forming with their contents the "corpuscles of Purkinje," these are likewise present, of similar size and form, in the "cement," and are its chief characteristic as a constituent of the tooth. The hardening material of the cement is partly segregated and combined with the parietes of the radiated cells and canals, and is partly contained in disgregated granules in the cells, which are thus rendered white and opaque, viewed by reflected light. The relative density of the dentine and cement varies according to the proportion of the earthy material, and chiefly of that part which is combined with the animal matter in the walls of the cavities, as compared with the size and number of the cavities themselves. In the complex grinders of the elephant, the masked boar, and the capybara, the cement, which forms nearly half the mass of the tooth, wears down sooner than the dentine.

The "*enamel*" is the hardest constituent of a tooth, and, consequently, the hardest of animal tissues; but it consists, like the other dental substances, of earthy matter arranged by organic forces in an animal matrix. Here, however, the earth is mainly contained in the canals of the animal membrane; and, in mammals and reptiles, completely fills those canals, which are comparatively wide, whilst their parietes are of extreme tenuity. The hardening salts of the enamel are not only present in far greater proportion than in the other dental tissues; but, in some animals, are peculiarly distinguished by the presence of fluate of lime.

The following are characteristic examples of the above-defined tissues, and their different combinations, in different teeth.

The examples are extremely few, and, as far as I know, are peculiar to the class *Pisces*, of calcified teeth which consist of a single tissue, and this is always a modification of dentine. The large pharyngeal teeth of the Wrasse (*Labrus*) consist of a very hard kind of unvascular dentine. *Fig.* 544. shows a vertical section of one of these teeth, supported upon the very vascular osseous tissue of the pharyngeal bone: *p* is the pulp cavity.

Fig. 544.



Section of pharyngeal tooth of Labrus, magnified. (*Owen's Odontography.*)

The next stage of complexity is where a portion of the dentine is modified by vascular canals. Teeth, thus composed of dentine and vaso-dentine, are very common in fishes. The hard dentine is always external, and holds the place, and performs the office, of enamel in the teeth of higher animals; but it is only analogous to enamel, not the same

predominates that the tissue takes a polish like enamel, for which it has commonly been mistaken in the teeth of fishes: I have called it "vitro-dentine."

The molars of the Dugong are examples of teeth composed of dentine and cement, the latter tissue forming a thick external layer. *Fig.* 546. A. is a transverse section of the crown of the second molar, natural size; and B. a magnified view of a portion of the section; *d* the dentine. remarkable for the number of minute calcigerous cells at its periphery; and *c* the cement.

In the great teeth of the lower jaw of the Cachalot, the pulp-cavity of the growing tooth becomes filled up by osteo-dentine, the result of a modified calcification of the dentinal pulp; and the full-grown tooth presents three tissues, as shown

* Odontography, pp. 17, 37.

in *fig.* 547., in which *c* is the thick external cement, *d* the hard dentine, and *o* the osteo-dentine; sometimes developed in loose stalactitic-shaped nodules.

In the teeth of the Sloth, and its great extinct congener, the Megatherium, the hard dentine is reduced to a thin layer, and the chief bulk of the tooth is made up of a central body of vaso-dentine, and a thick external crust of cement. *Fig.* 548. represents a

Fig. 548.

longitudinal section of a lower molar of the Megatherium, of half the natural size: *v* is the vaso-dentine, *d* is the hard dentine, and *c* is the cement; *p* is the base of the wide persistent pulp-cavity.

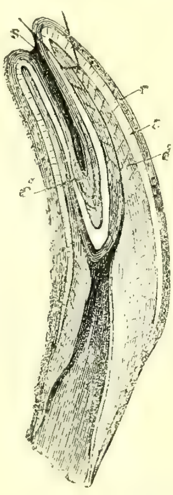
The hard dentine is, of course, the firmest tissue of a tooth so composed, and forms the crest of the transverse ridges of the grinding surface, like the enamel plates in the elephant's grinder. It has, consequently, been described to be enamel*, but its relation to that tissue is only one of analogy or function.

The human teeth, and those of the carnivorous mammals, appear at first sight to be composed of dentine and enamel only, as they were described to be by the Cuviers †, who called them, therefore, simple teeth; but their crowns are originally, and their fangs are always, covered by a thin coat of cement. There is also commonly a small central tract of osteo-dentine in old teeth.

In *fig.* 7, pl. 122, of my Odontography is given a longitudinal section of a human molar tooth, in which *d* is the dentine, *e* the enamel, and *c* the cement.

The teeth, called by Cuvier compound or complex in Mammalia, differ, as regards their composition, from the preceding, only by the different proportion and disposition of the constituent tissues. *Fig.* 549. is a longitudinal section of the incisor of a horse; *d* is the dentine, *e* the enamel, and *c* the cement; *c′* is the layer of cement reflected into the deep central depression of the crown; and *s* is the coloured mass of tartar and particles of food which fills up that cavity, forming the "mark" of the horse-dealer. The characteristic structure of the three tissues is shown in the magnified part of the section, *fig.* 550.

Fig. 549.



Section of incisor of a Horse (Equus).

A very complex tooth may be formed out of two tissues by the way in which these may be interblended, as the result of an original complex disposition of the constituents of the dental matrix.

Certain fishes, and a singular family of gigantic extinct Batrachians, which I have called "Labyrinthodonts,"* exhibit, as the name implies, a remarkable instance of this kind of complexity. *Fig.* 551. is a view of a canine tooth of the *Labyrinthodon salamandroïdes*, of the natural size; and *fig.* 552. is a slightly magnified view of a transverse section across the part of the crown marked *a*. At first view, the tooth appears to be of the simple conical kind, with the exterior surface merely striated longitudinally, but every streak is a fissure into which the very thin external layer of cement (*c*) is reflected into the body of

* Cuvier, Ossemens Fossiles, 4to, t. v., pt. 1., p. 172.; and Clift, Transactions of the Geological Society, 1835, p. 438.

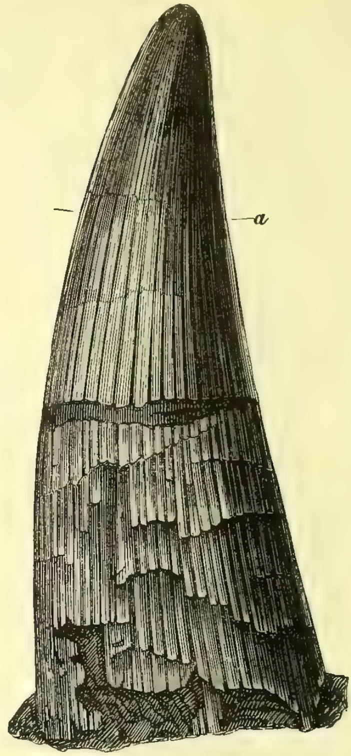
Fig. 551.

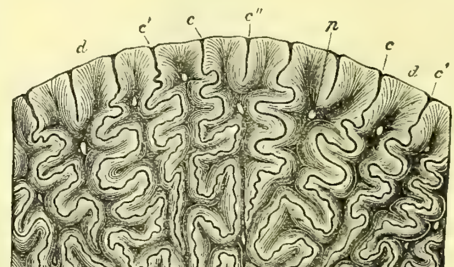


Tooth of a Labyrinthodon, natural size.

the tooth, following the sinuous wavings of the lobes of dentine (*d*), which diverge from the central pulp-cavity, *a*.

The inflected fold of cement *c* runs straight for about half a line, and then becomes wavy, the waves rapidly increasing in breadth as they recede from the periphery of the tooth ; the first two, three, or four undulations are simple ; then their contour itself becomes broken by smaller or secondary waves ; these become stronger as the fold approaches the centre of the tooth, when it increases in thickness, and finally terminates by a slight dilatation or loop close to the pulp-cavity, from which the free margin of the inflected fold of cement is separated by an extremely thin layer of dentine. The number of the inflected converging folds of dentine is about fifty at the middle of the crown of the tooth figured, but is greater at the base. All the inflected folds of cement at the base of the tooth have the same complicated disposition with increased extent; but, as they approach their termination towards the upper part of the tooth, they also gradually diminish in breadth, and consequently penetrate to a less distance into the substance of the tooth. Hence, in such a section as is delineated (*fig.* 552.), it will be observed that some of the convoluted folds, as those marked *c c*, extend near to the centre of the tooth; others, as those marked *c′*, reach only about half-way to the centre; and those folds, *c″*, which, to use a geological expression, are "cropping out," penetrate to a very short distance into the dentine, and resemble, in their extent and

Fig. 552.



Transverse section of tooth of Labyrinthodon. (*Magnified.*)

simplicity, the converging folds of cement in the fangs of the tooth of the Ichthyosaurus.

The disposition of the dentine is still more complicated than that of the cement. It consists of a slender, central, conical column, excavated by a conical pulp-cavity for a certain distance from the base of the tooth; and this column sends radiating outwards, from its circumference, a series of vertical plates, which divide into two once or twice before they terminate at the periphery of the tooth.

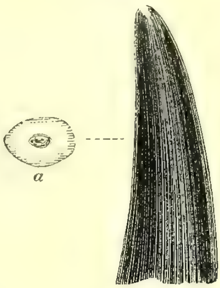
Each of these diverging and dichotomising plates gives off throughout its course smaller processes, which stand at right angles, or nearly so, to the main plate; they are generally opposite, but sometimes alternate; many of the secondary plates or processes, which are given off near the centre of the tooth, also divide into two before they terminate; and their contour is seen, in the transverse section, to partake of all the undulations of the folds of cement which invest and divide the dentinal plates and processes from each other.

The dental pulp-cavity is reduced to a mere line about the upper third of the tooth, but throughout its whole extent fissures radiate from it, corresponding in number with the radiating plates of dentine. Each fissure is continued along the middle of each plate, dividing where this divides, and extending along the middle of each bifurcation and process to within a short distance of the line of cement. The pulp-fissure commonly dilates into a canal at the origin of the lateral processes of the radiating plates, before it divides to accompany and penetrate those processes.

The main fissures or radiations of the pulp-cavity extend to within a line or half a line of the periphery of the tooth, and suddenly dilate at their terminations into spaces, which, in transverse section, are subcircular, oval, or pyriform, *p*: the branches of the radiating lines, which are continued into the lateral secondary plates or processes of the dentinal lamellæ, likewise dilate into similar, and generally smaller spaces. All these spaces, or canals, in the living tooth, must have been occupied by corresponding processes of the vascular pulp: they constitute so many centres of radiation of the fine calcigerous tubes, which, with their uniting clear substance, constitute the dentine.*

An analogous complexity is produced by numerous fissures radiating from a central mass of vaso-dentine, which more or less fills up the pulp-cavity of the seemingly simple conical teeth of the extinct family of fishes which I have called "Dendrodonts."† *Fig.* 553. is one of these fossil teeth, of the natural size; *a* a transverse section; and *fig.* 554 a reduced view of a portion of the same section, enlarged twenty diameters.

Fig. 553.



Tooth of a Dendrodus, natural size.

Thus magnified, a central pulp-cavity, of relatively small size, and of an irregular lobulated form, is discerned, a portion of which

† Ib. p. 171.

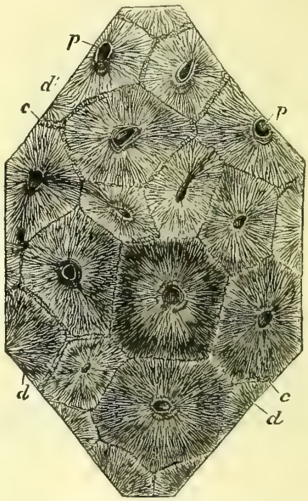
is shown at p; this is immediately surrounded by the transverse sections of large cylindrical medullary, or pulp-canals of different sizes; and, beyond these, there are smaller and more numerous medullary canals, which are processes of the central pulp-cavity. In the transverse section these processes are seen to be connected together by a net-work of smaller medullary canals belonging to a coarse osseous texture into which the pulp has been converted, and this structure occupies the middle half of the section. All the medullary canals were filled by the opaque matrix. From the circumference of the central net-work, straight medullary fissures radiate at pretty regular intervals to the periphery of the tooth: most of these canals divide once, rarely twice, in their course; the division taking place sometimes at their origin, in others at different distances from their terminations, and the branches diverge slightly as they proceed. Each of the above medullary fissures is continued from a short process of the central structure, which is connected by a concave line with the adjoining process, so that the whole periphery of the transverse section of the central coarse reticulo-medullary body of the tooth presents a crenate outline. From each ray and its primary dichotomous divisions, short branches are sent off at brief intervals, generally at right angles with the trunk, or slightly inclined towards the periphery of the tooth. These subdivide into a few short ramifications, like the branches of a shrub, and terminate in irregular and somewhat angular dilatations, simulating leaves, but which resolve themselves into radiating fasciculi of calcigerous tubes. There are from fifteen to twenty-five or thirty-six of these short and small lateral branches on each side of the medullary rays.

A third kind of complication is produced by an aggregation of many simple teeth into a single mass.

The examples of these truly compound teeth* are most common in the class of Fishes, but the illustration here selected is from the Mammalian class. Each tooth of the Cape Ant-eater (*Orycteropus*) presents a simple form, is deeply set in the jaw, but without dividing into fangs; its broad and flat base is porous, like the section of a common cane. The canals to which these pores lead contain processes of a vascular pulp, and are the centres of radiation of as many independent series of dentinal tubules. Each tooth, in fact, consists of a congeries of long and slender prismatic denticles of dentine, which are cemented together by their ossified capsules, the columnar denticles slightly decreasing in diameter and occasionally bifurcating as they approach the grinding surface of the tooth.

A figure of a longitudinal section of the molar teeth is given in Pl. 76, *fig.* 10. of my "Odontography," and a magnified view of a similar section in Pl. 77.; *fig.* 555. gives a magnified view of a portion of the transverse

Fig. 555.



Part of transverse section of the tooth of the Orycteropus. (Magnified.)

section of the fourth molar, showing *c* the cement; *d* the dentine; *p* the pulp-cavity of the denticles; and *d'* a section of one of the denticles just beyond its bifurcation.

The pectinated incisors of the flying Lemur of the Indian Islands (*Galeopithecus*) are examples of teeth, the crowns of which are composed of denticles consisting of hard dentine, with a covering of true enamel. The layer of cement over this is too thin to show its characteristic structure, and does not fill up the intervals of the denticles, which stand out as free processes from the base of the crown. Tubular prolongations of the pulp-cavity are continued up the centre of each denticle.

Fig. 556. exhibits a longitudinal section, magnified, of this kind of compound tooth; *d* is the dentine; *e* the enamel; *p* the pulp-cavity. The originally detached summits of the crown of the human incisor are homologous with these columnar processes, or denticles of the incisor of the *Galeopithecus*.

In the compound molars of the great African wart-hogs (*Phacochœrus*) the columnar denticles are in three rows, and their interspaces are filled up by cement: each denticle consists of a slender column of hard dentine inclosed in a thick sheet of enamel, the whole being bound together by the cement; and the

* In the "Leçons d'Anatomie Comparée" of Cuvier, the teeth, in which folds of enamel and cement penetrate the entire substance of the crown, are called "compound:" "Nous appellons 'dent composée' celle dont les différentes substances forment des replis tellement profonds, que dans quelque sens qu'on coupe la dent, on coupe plusieurs fois chacune des substances qui la composent: telles sont les dents molaires de l'*Éléphant*." The teeth of the "Labyrinthodonts" would come under this definition more truly than those of the elephant, although they differ from them in having no enamel; for a molar of an elephant might be bisected, vertically and transversely, without cutting the tissues across more than once.

denticles, as in the *Galeopithecus*, blending together into a common base in the fully-developed tooth.

Fig. 556.

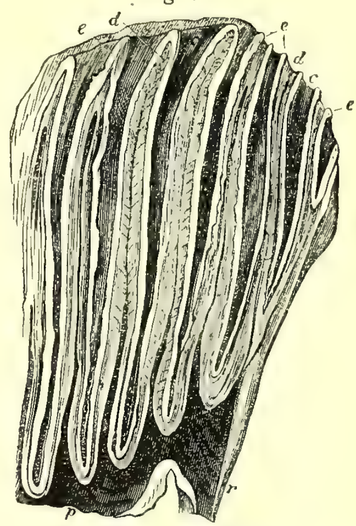
lasii, in Pl. 140, *fig*. 4, of my " Odontography."

In the elephant the denticles of the compound molars are in the form of plates, vertical to the grinding surface and tranverse to the long diameter of the tooth. When the tooth is bisected vertically and lengthwise, the three substances, *d* dentine, *e* enamel, and *c* cement,

Fig. 557.



Section of molar of Elephant.

are seen interblended as in *fig*. 557., in which *p* is the common pulp-cavity, and *r* one of the roots of this complex tooth.

A still more complex grinding apparatus is found in certain fishes. The lower pharyngeal bone of the parrot-fish (*Scarus**), for example, supports a dental plate with a triturating surface like that of the compound molars of the *Phacochærus*. The interlocked upper pharyngeals (*fig*. 565.) support dental

* Odontography, pl. 51., fig. 3.

masses with a grinding surface more like that of the compound molars of the elephant.

When a vertical and longitudinal section is made of one of these upper pharyngeal compound teeth, each denticle is seen to be composed, as in *fig.* 558., of a body of very hard and unvascular dentine *d*, with a thick sheath of enamel *e*, the denticles being united together by the cement *c*, and supported and further united together, and to the pharyngeal bone, by a basal mass of vascular osteo-dentine.

Such are some of the prominent features of a field of observation which comparative anatomy opens out to our view; — such the varied nature, and such the gradation of complexity of the dental tissues, which, up to December 1839*, continued, notwithstanding successive approximations to the truth, to be described in systematic works as a "phaneros," or "a dead part or product exhaled from the surface of a formative bulb!" The truth may be slowly but is surely established, subject to the usual attempts to mask or detract from the merit of the discovery. By no systematic authors has the hypothesis of the formation of dentine by transudation or secretion been more frequently or more explicitly enunciated than by the Cuviers. Baron Cuvier repeats, in both editions of his elaborate work — the "Ossemens Fossiles" — "C'est dans ce vide conçevable que se déposeront les matières qui doivent former la dent, savoir: la substance vulgairement appelée *osseuse*, qui sera transudée par des productions gelatineuses venant du fond de la capsule, et l'émail qui sera déposé par les cloisons membraneuses," t. ii. p. 61., ed. 1812.; t. i. p. 33., ed. 1821. See, also, M. F. Cuvier, "Dents de Mammifères," 8vo, 1825. "L'ivoire se dépose par couches concentriques," p. xxvii.; "L'émail se dépose dans un sens contraire à l'ivoire," ib. p. xxviii. And Baron Cuvier again, in the second edition of his "Leçons d'Anatomie Comparée," t. iv. 1836, p. 214: "L'ivoire se dépose par couches, par une sorte de transudation." In the first edition of this classical work, Cuvier had illustrated the peculiarity of the teeth of certain fishes, which are at first detached and afterwards united to the jaw-bone, by comparing their growth to that of the epiphyses of the long bones: "Mais les dents qui ne tiennent qu'à la gencive seulement, comme celle des *Squales*, croissent à la manière des epiphyses des os, c'est-à-dire que toute leur substance osseuse est d'abord tendre et poreuse, et qu'elle se durcit uniformément, et finit par devenir entièrement dure comme de l'ivoire," t. iii. 1805, p. 112. Whether the great anatomist meant to imply that the osseous tissue of the epiphyses of bones was developed differently from osseous tissue in general, *e. g.* by the uniform and simultaneous hardening or calcification, obscurely referred to in the above quotation, may be questioned, for such is not the way in which the teeth of the shark are calcified. But this is certain, that the idea, whatever it might have been, had no influence on the fixed belief of the developement of the dental tissue by transudation expressed in their later and more elaborate works by Baron Cuvier and his accomplished brother; and, in point of fact, the passage which I have quoted is expunged from the second edition of the "Leçons d'Anatomie Comparée," 1835: the successive stages of calcification in the different teeth of the same vertical series in the jaw of the shark, having probably been noticed in the interim by Cuvier.

The author of the article "Sécrétions" in the "Dictionnaire Universel d'Histoire Naturelle," has, however, reproduced Cuvier's obscure comparison of certain fishes' teeth to the epiphyses of bone, as evidence of the needlessness of any ulterior researches for the demonstration of the theory of dental developement by conversion and calcification of the pulp. The passage from the third vol. of the old edition (1800) of the "Leçons d'Anat. Comp.," p. 112, is cited to show that it naturally conducts to the knowledge of such mode of developement of dentine: "En 1840 et 1841 (the 'Comptes Rendus de l'Acad. des Sciences' give the true date) l'étude des dents de Squale par M. R. Owen, lui a démontrée leur accroissement par intussusception, comme elle avait été à G. Cuvier trente-cinq années auparavant." How or why G. Cuvier came to abandon the theory so demonstrated, and how it happened that none of his contemporaries adopted it, M. Duvernoy does not explain. He does give a reason for the omission, in the second edition of the "Leçons d'Anat. Comp." of the passage which he affirms to contain the demonstration: "Malheureusement, le copiste de cet ancien texte pour la 2de édition a omis ce passage, par oubli." It was natural to conclude that its obscurity and seeming contradiction to the theory of dental developement, formally propounded by Cuvier, as well as to the facts shown by nature in the sharks, had been the cause of its omission; but even had the misfortune to which M. Duvernoy now attributes that omission (for in the copious list of addenda and corrigenda to the fifth, 1837, and final, 1846, volumes it is not noticed) not occurred, the coincidence of such passages as the following would still have been inexplicable and irreconcilable with the deductions that M. Dumeril is now enabled to draw from the comparison of the shark's tooth with the epiphyses of long bones. "L'ivoire se dépose par couches, par une sorte de transudation." Leçons d'Anat. Comparée, t. iv., 1836, p. 214. To which proposition Cuvier has himself added a note: "Je me suis assuré récemment, sur des germes de dents d'éléphant, que la substance osseuse de la dent se forme comme

* See the Fasciculus of M. de Blainville's great work, "Ostéographie et Odontographie d'Animaux Vertébrés," which he submitted to the Academy of Sciences of the Institute of France on the same day, December 16th, 1839, on which I communicated, on the occasion of my election as corresponding member of that body, my "Theory of the development of dentine by centripetal calcification and conversion of the cells of the pulp."

les coquilles." And the editor (M. Duvernoy), in order to obviate any possibility of misconception, has himself subjoined a note to that passage, as follows: "L'*ivoire* a été aussi appellé *substance osseuse*, à cause de son analogie de composition chimique et de dureté avec les os. Mais la nature inerte et inorganique de cette substance, mieux appreciée dans ces derniers temps, surtout par les travaux de M. Cuvier, ne permet plus de la désigner, avec justesse, par cette seconde expression. Du moins est-il nécessaire de prémunir le lecteur contre l'ideé fausse qu'il pourrait en tirer, qu'elle serait organisée, qu'elle se développerait à la manière des os."—Tom. cit. p. 201, (1836). In the same spirit in which M. Duvernoy sees (in 1848) that a true idea, instead of a false one, may be drawn from casual expressions and similies loosely applied in the old Leçons of 1800 and 1805; others have sought to depreciate the value of the establishment of the truth by citing the doubts, or tentative approximations made by Purkinje and Schwann to my theory, interpreting such approximations by the light of the established truth. So far from finding such a resting-place for doubt in Cuvier's early simile, cited by M. Duvernoy in 1848, or in the interrogatories of Schwann, nothing short of the investigation of the whole of this vast subject, zootomically, developmentally, and microscopically, as narrated in my "Odontography," sufficed to settle my own doubts; and nothing short of the evidence and illustrations given in that work appeared to me adequate to convert anatomists from the excretion-hypothesis to the intussusception theory.

That the dentine is the ossified pulp is an older notion than that it is an inorganic secretion from such pulp. But an hypothesis, to be of any value in science, must be proved. Almost every true theory has been indicated, with various degrees of approximation, before its final establishment: but he has ever been held, in exact philosophy, to be the author of a theory, by whom it has been first rightly enunciated and satisfactorily established. When time has dissipated the mists of individual or national rivalries and jealousies, the name of the true discoverer is clearly seen by the inextinguishable light of true and impartial history: and to that period I look forward with calm and confident hope.

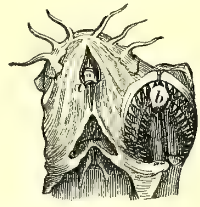
I proceed now to briefly point out the leading characteristics of the teeth in the different classes of the vertebrate animals.

Dental System of Fishes.

The teeth of fishes, whether we study them in regard to their number, form, substance, structure, situation, or mode of attachment, offer a greater and more striking series of varieties than do those of any other class of animals.

As to *number*, they range from zero to countless quantities. The Lancelet, the Ammocete, the Sturgeon, the Paddle-fish, and the whole order of *Lophobranchii*, are edentulous. The Myxinoids have a single pointed tooth on the roof of the mouth (*fig.* 559., *a*), and two serrated dental plates (*b*) on the

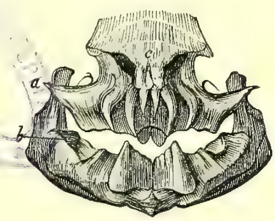
Fig. 559.



Myxine. (*Müller.*)

tongue. The Tench (*fig.* 514. Vol. III. p. 979. art. Pisces)* has a single grinding tooth on the occiput (*c*), opposed to two dentigerous pharyngeal jaws below (*dd*). In the Lepidosiren a single maxillary dental plate (*fig.* 560., *a*) is opposed to a single mandibular

Fig. 560.



Lepidosiren.

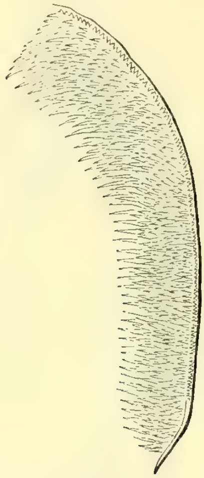
one (*b*), and there are two small denticles on the nasal bone (*c*). In the extinct Sharks with crushing teeth, called *Ceratodus* and *Ctenodus*, the jaws were armed with four teeth, two above and two below.† In the *Chimæræ*, two mandibular teeth are opposed to four maxillary teeth.‡ From this low point the number in different fishes is progressively multiplied until, in the Pike, the Siluroids (*fig.* 561.), and many other fishes, the mouth becomes crowded with countless teeth.

With respect to *form*, I may first observe, that as organised beings withdraw themselves more and more, in their ascent in the scale of life, from the influence of the general polarising forces, so their parts progressively deviate from geometrical figures: it is only, therefore, in the lowest vertebrated class that we find teeth in the form of perfect cubes, and of prisms or plates with three sides (*Myletes*), four sides (*Scarus*), five or six sides, *Myliobates* (*fig.* 562.). The cone is the most common form in fishes: such teeth may be slender, sharp-pointed, and so minute, numerous, and closely aggregated, as to resemble the plush or pile of velvet; these are called "villiform teeth" (*dentes villiformes, dents en velours*§); all the teeth of the Perch are of this kind:

* And Odontography, pl. 57. *fig.* 5.
† See Odontography, pl. 22, *figs.* 2. 6, 7.
‡ Ib., pl. 28, *figs.* 1, 2. 4. 6.
§ The French terms are those used by Cuvier and Valenciennes in their great "Histoire des Poissons," 4to.

when the teeth are equally fine and numerous, but longer, they are called "ciliiform" (*dentes*

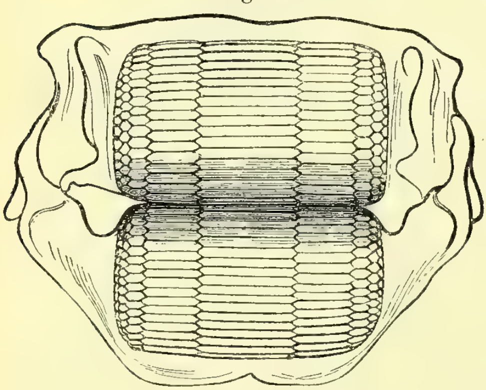
Fig. 561.



Palatine bone and teeth (*Silurus*).

ciliiformes): when the teeth are similar to, but rather stronger than these, they are called

Fig. 562.



Jaws and teeth (*Myliobates*).

"setiform" (*dentes setiformes, dentes en brosse*): conical teeth, as close set and sharp pointed as the villiform teeth, but of larger size, are called "rasp-teeth" (*dentes raduliformes, dents en rape* or *en cardes, fig.* 561.); the Pike presents such teeth on the back part of the vomer: the teeth of the Sheat-fish (*Silurus glanis*) present all the gradations between the villiform and raduliform types. Setiform teeth are common in the fishes thence called Chætodonts*; in the genus *Citharina* they bifurcate at their free extremities; in the genus *Platax* they end there in three diverging points (*fig.* 563.), and the cone here merges into the long and slender cylinder. Sometimes the cone is compressed into a slender trenchant blade: and this may be pointed and

* Χαίτη, bristle; ὀδοὺς, tooth.

recurved, as in the *Muræna;* or barbed, as in *Trichiurus*, and some other Scomberoids; or it may be bent upon itself, like a tenterhook, as in the fishes thence called Goniodonts.* In the Bonito may be perceived a progressive thickening of the base of the conical teeth: and this being combined in other predatory

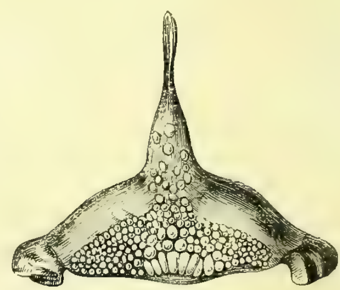
Fig. 563.

Mandibular teeth, magnified (*Platax*).

fishes with increased size and recurved direction, they then resemble the laniary or canine teeth of carnivorous quadrupeds, as we see in the large teeth of the Pike, in the Lophius†, and in certain sharks.‡

The anterior diverging grappling teeth of the wolf-fish form stronger cones; and by progressive blunting, flattening, and expansion of the apex, observable in different fishes, the cone gradually changes to the thick and short cylinder, such as is seen in the back

Fig. 564.



Inferior pharyngeal bone and teeth (*Labrus*).

teeth of the wolf-fish, and in similar grinding and crushing teeth in other genera, whether feeders on sea-weeds, or crustaceous and testaceous animals. The grinding surface of these short cylindrical teeth may be convex, as in the Sheep's-head fish (*Sargus*); or flattened, as in the pharyngeal teeth of the Wrasse (*Labrus*).§ Sometimes the hemispheric teeth are so numerous, and spread over so broad a surface, as to resemble a pavement, as in the pharyngeal bones of the Wrasse or Rock-fish (*Labrus, fig.* 564.); or they may be so small, as well as numerous (*dentes graniformes*), as to give a granulated surface to the part of the mouth to which they are attached (premaxillaries of *Cossyphus*).‖ A progressive increase

* Γωνία, an angle; ὀδοὺς, a tooth.
† Vol. III., *fig.* 512, p. 978. art. Pisces.

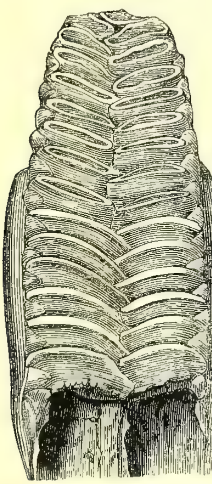
§ Ib. *fig.* 513, p. 978.
‖ Odontography, pl. 45, *fig.* 1.

of the transverse over the vertical diameter may be traced in the molar teeth of different fishes, and sometimes in those of the same individual, as in *Labrus* (*fig.* 564.), until the cylindrical form is exchanged for that of the depressed plate. Such dental plates (*dentes lamelliformes*) may be found, not only circular, but elliptical, oval, semilunar, sigmoid, oblong, or even square, hexagonal, pentagonal, or triangular; and the grinding surface may present various and beautiful kinds of sculpturing. The broadest and thinnest lamelliform teeth are those that form the complex grinding tubercle of the Diodon.* The front teeth of the Flounder and Sargus present the form of compressed plates, at least in the crown, and are true *dentes incisivi.* Numerous wedge-shaped dental plates (*dentes cuneati*) are set vertically in the upper pharyngeal bones of the Parrot-fish (*Scarus*, *fig.* 565.). A thin

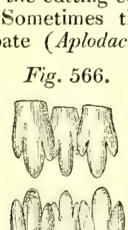
Fig. 565.



Superior pharyngeal bones and teeth (*Scarus*).

lamella, slightly curved like a finger-nail, is the singular form of tooth in an extinct genus of fishes, which I have thence called *Petalodus.* Sometimes the incisive form of tooth is notched in the middle of the cutting edge, as in *Sargus unimaculatus.* Sometimes the edge of the crown is trilobate (*Aplodactylus*, *fig.* 566.).

Fig. 566.



Front teeth of Aplodactylus.

Sometimes it is made quinquelobate by a double notch on each side of the large middle lobe (*Boops*). In the formidable Sea-pike (*Sphyræna Barracuda*) the crown of each tooth, large and small, is produced into a compressed and sharp point, and resembles a lancet. Sometimes the edges of such lancet-shaped teeth are finely serrated, as in *Priodon*, and the great Sharks of the genus *Carcharias*, the fossil teeth of which indicate a species (*Carch. Megalodon*) sixty or seventy feet in length.

The lancetted form is exchanged for the stronger spear-shaped tooth in the Sharks of the genus *Lamna;* and in the allied great extinct *Otodus*, as in the small Porbeagle, similarly shaped, but stronger, piercing and cutting teeth were complicated by one or more accessory compressed cusps on each side their base, like the Malay crease.

With respect to *situation*, the teeth, in Sharks and Rays, are limited to the bones (maxillary and mandibular), which form the anterior aperture of the mouth: in the Carp and other Cyprinoids the teeth are confined to the bones (pharyngeal and basi-occipital) which circumscribe the posterior aperture of the mouth. The Wrasses (*Labrus*) and the Parrot-fishes (*Scarus*) have teeth on the pre-maxillary and pre-mandibular, as well as on the upper and lower pharyngeals; both the anterior and posterior apertures of the mouth being thus provided with instruments for seizing, dividing, or comminuting the food, the grinders being situated at the pharynx. In most fishes teeth are developed also in the intermediate parts of the oral cavity, as on the palatines, the vomer, the hyoid bones, the branchial arches; and, though less commonly, on the pterygoids, the entopterygoids, the sphenoids, and even on the nasal bone (*fig.* 560, *c.*). It is very rare to find teeth developed on the true superior maxillary bones; but the Herring and Salmon tribes, some of the Ganoid Fishes, and the great *Sudis*, are examples of this approach to the higher Vertebrata. Among the anomalous positions of teeth may be cited, besides the occipital alveolus of the Carp*, the marginal alveoli of the prolonged, depressed, well ossified rostrum of the Saw-fish, *Pristis.* In the Lampreys and in *Helostomus* (an osseous fish), most of the teeth are attached to the lips. Lastly, it is peculiar to the class *Pisces*, amongst Vertebrata, to offer examples of teeth developed in the median line of the mouth, as in the palate of the Myxines (*fig.* 559, *a.*); or crossing the symphysis of the jaw, as in *Notidanus*, *Scymnus*, and *Myliobates.*

Nor is the mode less varied than the place of attachment. The teeth of *Lophius*, *Pœcilia*, *Anableps*, are always moveable. In most fishes they are anchylosed to the jaws by continuous ossification from the base of the dental pulp; the histological transition being more or less gradual from the structure of the tooth to that of the bone. Sometimes we find, not the base, but one side of the tooth anchylosed to the alveolar border of the jaw; and the teeth oppose each other by

† Odontography, pl. 38, *fig.* 2; and art. PISCES, Vol. III. p. 980, *fig.* 517.

* Odontography, pl. 8; and art. PISCES, Vol. III., p. 980, *fig.* 518.

their sides instead of their summits (*Scarus**); in *Pimelodus*, however, where the teeth are thus attached, the crown is bent down in the upper teeth, and bent up in the lower ones, at right angles to the fang, so that they oppose each other by the normal surfaces. Certain teeth of recent and fossil cartilaginous fishes have their base divided into processes like fangs, but these serve for the attachment of ligaments, and are not set in bony sockets like the true fangs or roots of the teeth of the Mammalia. Some Sharks have two divaricating fangs; some fossil teeth referred to my genus *Petalodus* by Agassiz, with the specific name "*radicans*," have the base divided into several fangs or processes, indicating a generic distinction. The base of anchylosed teeth is, at first, attached to the jaw-bone by ligament; and in the Cod-fish, Wolf-fish, and some other species, as calcification of the tooth progresses towards its base, the subjacent portion of the jaw-bone receives a stimulus, and developes a process corresponding in size and form with the base of the tooth: for some time a thin layer of ligamentous substance intervenes, but anchylosis usually takes place to a greater or less extent before the tooth is shed. Most of the teeth of the Lophius retain the primitive ligamentous connection; the ligaments † of the large internal or posterior teeth of the upper and lower jaws, radiate on the corresponding sides of the bone, the base of the tooth resting on a conformable alveolar process. The ligaments do not permit the tooth to be bent outwards beyond the vertical position, but yield to pressure in the contrary direction, by which the point of the tooth may be directed towards the back of the mouth; the instant, however, that the pressure is remitted, the tooth returns through the elasticity of the bent ligaments, as by the action of a spring, into its usual erect positions (*fig.* 512, *c. c.* Vol. III. p. 978. art. PISCES); the deglutition of the prey of this voracious fish is thus facilitated, and its escape prevented.‡ The broad and generally bifurcate bony base of the teeth of Sharks is attached by ligament to the semi-ossified crust of the cartilaginous jaws §; but they have no power of erecting or depressing the teeth at will. The small and closely crowded teeth of Rays are also connected by ligaments to the subjacent maxillary and mandibular membranes. The broad tesselated teeth of the *Myliobates* have their attached surface longitudinally grooved to afford them better hold-fast, and the sides of the contiguous teeth are articulated together by serrated or finely undulating sutures, a structure unique in dental organisation.‖ The teeth of the *Sphyræna* are examples of the ordinary implantation in sockets, with the addition of a slight anchylosis of the base of the fully-formed tooth with the alveolar parietes; and the compressed rostral teeth of the Saw-fish are deeply implanted in sockets. In the latter the hind margin of their base is grooved, and a corresponding ridge from the back part of the socket fits into the groove, and gives additional fixation to the tooth. Some implanted teeth in the present class have their hollow base further supported, like the claws of the feline tribe, upon a bony process arising from the base of the socket; the incisors of the Balistes, *e.g.*, afford an example of this double or reciprocal gomphosis. In fact, the whole of this part of the organisation of fishes is replete with beautiful instances of design, and instructive illustrations of animal mechanics. The vertical section of a pharyngeal jaw and teeth of the Wrasse (*Labrus* *) would afford the architect a model of a dome of unusual strength, and so supported as to relieve from pressure the floor of a vaulted chamber beneath. The base of the dome-shaped tooth is slightly contracted, and is implanted in a shallow circular cavity; the rounded margin of which is adapted to a circular groove in the contracted part of the base; the margin of the tooth which immediately transmits the pressure of the bone, is strengthened by an inwardly projecting convex ridge. The masonry of this inner buttress, and of the dome itself, is composed of hollow columns, every one of which is placed so as best to resist or transmit in the due direction the external pressure. The floor of the alveolus is thus relieved from the office of sustaining the tooth: it forms, in fact, the roof of a lower vault, in which the germ of a successional tooth is in course of development; had the crushing tooth in use, rested, as in the Wolf-fish, by the whole of its base upon the alveolus, the supporting plate, gradually undermined by the growth of the new tooth, must have given way, and been forced upon the subjacent delicate and highly vascular and sensitive matrix of the half-formed tooth. But the superincumbent pressure is exclusively sustained by the border of the alveolus, whence it is transferred to the walls dividing the vaulted cavities containing the germs of the new teeth; the roofs of these cavities yield to the absorbent process consequent on the growth of the new teeth without materially weakening the attachment of the old teeth, and without the new teeth being subjected to any pressure until their growth is sufficiently advanced to enable them to bear it with safety; by this time the sustaining borders of the old alveolus are undermined, and the old worn-down tooth is shed.

The singular and powerfully developed dental system of the Wolf-fish (*Anarrhichas Lupus*) has been a subject of interest to many anatomists. The general character and physiological relations of the teeth in this species had not escaped the attention of Hunter. In his paper on the Gillaroo trout, read before the Royal Society in 1774, he observes that "the teeth of fishes which subsist

* Odontography, pl. 49; and art. PISCES, Vol. III. *fig.* 516, p. 979.

† See art. PISCES, Vol. III., *fig.* 512 *d*, p. 978.

§ Art. PISCES, Vol. III., *fig.* 510, p. 976.

‖ Odontography, p. 46. pl. 27 *c*.

* *Fig.* 544; and art. PISCES, Vol. III., *fig.* 513, p. 978.

chiefly on animal matter must vary according as their food may be common salt fish, or shell-fish." "Such fish as live on the first kind have, like the carnivorous quadrupeds and birds, no apparatus for mastication, their teeth being intended merely for catching the food and fitting it to be swallowed. But the shells of the second kind of food render some degree of masticatory power necessary to fit it for its passage either into the stomach or through the intestines: and accordingly we find in certain fish a structure suited to the purpose. Thus the mouth of the Wolf-fish is almost paved with teeth, by means of which it can break shells to pieces, and fit them for the œsophagus of the fish, and so effectually disengage the food from them, that though it lives upon such hard food, the stomach does not differ from that of other fish."

But in order to secure the capture of the shell-fish, the teeth of the Wolf-fish are not all crushers; some present the laniary type, with the apices more or less recurved and blunted by use, and consist of strong cones spread abroad, like grappling hooks, at the anterior part of the mouth.*

The premaxillary teeth are all conical, and arranged in two rows; there are two, three, or four in the exterior row, at the mesial half of the bone, which are the largest; and from six to eight smaller teeth are irregularly arranged behind. There are three large, strong, diverging laniaries at the anterior end of each premandibular bone, and immediately behind these an irregular number of shorter and smaller conical teeth, which gradually exchange this form for that of large obtuse tubercles; these extend backwards, in a double alternate series, along a great part of the alveolar border of the bone, and are terminated by two or three smaller teeth in a single row, the last of which again presents the conical form. Each palatine bone supports a double row of teeth, the outer ones being conical and straight, and from four to six in number; the inner ones two, three, or four in number, and tuberculate. I have seen a specimen where the inner row was wanting on one side. The lower surface of the vomer is covered by a double irregularly alternate series of the same kind of large tuberculate crushing teeth as those at the middle of the premandibular. All the teeth are anchylosed to more or less developed alveolar eminences, like the anterior teeth of the *Lophius*. The periphery of the expanded circular base of the large anterior grappling teeth is divided into processes indicative of the original ligamentous fasciculi at the base of the pulp by the ossification of which their anchylosis is effected.

When such anchylosed teeth and the supporting bone are divided by a vertical section, as in *fig.* 2, pl. 66, of my "Odontography," there may be generally discerned a faint transverse line indicating the original separation between the tooth and the bone, and more clearly defining the dental from the osseous structure, than in the anchylosed teeth of other fishes. From the enormous development of the muscles of the jaws, and the strength of the shells of the whelks and other testacea which are cracked and crushed by the teeth, their fracture and displacement must obviously be no unfrequent occurrence; and most specimens of the jaws of the Wolf-fish exhibit some of the teeth either separated at this line of imperfect anchylosis, or, more rarely, broken off above the base, or, still more rarely, detached by fracture of the supporting osseous alveolar process.

With regard to the *substance* of the teeth of fishes, the modifications of dentine, called vaso-dentine and osteo-dentine *, predominate much more than in the higher Vertebrata; and they thus more closely resemble the bones which support them. There is, however, great diversity in respect of substance. The teeth of most of the Chætodonts are flexible, elastic, and composed of a yellowish subtransparent albuminous tissue; such, likewise, are the labial teeth of the Helostome, the premaxillary and mandibular teeth of the Goniodonts, and of that percoid genus thence called *Trichodon*. In the Cyclostomes the teeth consist of a denser albuminous substance. The upper pharyngeal molar of the Carp consists of a peculiar brown and semitransparent tissue, hardened by salts of lime and magnesia. The teeth of the Flying-fish (*Exocœtus*), and Sucking-fish (*Remora*), consist of osteo-dentine. In many fishes, *e.g.* the *Acanthurus*, *Sphyræna*, and certain Sharks (*Lamna*, *fig.* 545.), a base, or body of osteo-dentine is coated by a layer of true dentine, but of unusual hardness, like enamel: in *Prionodon* this hard tissue predominates. In the *Labrus* the pharyngeal crushing teeth consist wholly of hard or unvascular dentine (*fig.* 544.). In most Pycnodonts and Cestracionts, and many other fishes, the body of the tooth consists of ordinary unvascular dentine, covered by a modification of that tissue which I have called "vitro-dentine" from its clear, polished, enamel-like character: but this is not enamel, nor the product of a distinct organ from the dentinal pulp: it differs from ordinary dentine in the greater proportion of the mineral particles, their more minute diffusion through the gelatinous basis, in the straighter course and more minute size of the calcigerous tribes; it results from the calcification of the external layer of the dentinal pulp, and is the first part of the tooth which is formed. In *Sargus* and *Balistes* the body of the tooth consists of true dentine, and the crown is covered by a thick layer of a denser tissue, developed by a distinct organ, and differing from the "enamel" of higher animals only in the more complicated and organised mode of deposition of the earthy salts. The ossification of the capsule of the complex matrix of these teeth covers the enamel with a thin coating of "cement." In the pharyngeal

* Odontography, pl. 60, 61.

* Odontography, Introduction, p. lxxii.

teeth of the *Scarus* a fourth substance is added by the ossification of the base of the pulp after its summit and periphery have been converted into hard dentine; and the teeth (*fig.* 558.), thus composed of cement (*c*), enamel (*e*), dentine (*d*), and osteo-dentine, are the most complex in regard to their substance that have yet been discovered in the animal kingdom.

The tubes which convey the capillary vessels through the substance of the osteo- and vaso-dentine of the teeth of fishes* were early recognised, on account of their comparatively large size; as by André, *e.g.* in the teeth of *Acanthurus*, and by Cuvier and Von Born in the teeth of the Wolf-fish and other species. Leeuwenhoek had also detected the much finer tubes of the peripheral dentine of the teeth of the Haddock. These "dentinal tubuli" are given off from the parietes of the vascular canals, and bend, divide, and subdivide rapidly in the hard basis-tissue of the interspaces of those canals in osteo-dentine; the dentinal tubuli alone are found in true dentine, and they have a straighter and more parallel course, usually at right angles to the outer surface of the dentine. Those conical teeth which, when fully formed, consist wholly or in great part of osteo-dentine or vaso-dentine, always first appear with an apex of hard or true dentine. In some fishes the simple central basal pulp-cavity of such teeth, instead of breaking up into irregular or parallel canals, sends out a series of vertical plates from its periphery, which, when calcified, give a fluted character to the base of the tooth, *e.g.* in *Lepidosteus oxyurus.*† Sometimes such radiating vertical basal plates of dentine are wavy in their course, and send off narrow processes from their sides; and, as a thin layer of the outer capsule interdigitates with the outstanding plates of the dentinal pulp, and becomes co-calcified with them, a transverse section of such a tooth presents a series of interblended wavy or labyrinthic tracts of thick dentine radiating from the centre, and of thin cement converging towards the centre of the tooth.‡ An analogous but more complicated structure obtains when the radiating, wavy, vertical plates of dentine dichotomise, and give off from their sides, throughout their course, numerous branch plates and processes, which are traversed by medullary sinuses and canals with their peripheral terminations dilated, and becoming the centres of lobes or columns of hard dentine. The transverse section of such teeth gives the appearance of branches of a tree, with leaf-stalks and leaves, radiating from the central pulp-cavity to the circumference of the tooth; and I have called the fossil fish in which this structure was first detected, *Dendrodus*.

Thus, with reference to the main and fundamental tissue of tooth, we find not fewer than six leading modifications in fishes;—hard or true dentine (*Sparoids, Labroids, Lophius, Balistes, Pycnodonts, Prionodon, Sphyræna, Megalichthys, Rhizodus, Diodon, Scarus*); osteo-dentine (*Cestracion, Acrodus, Lepidosiren, Ctenodus, Hybodus, Percoids, Sciænoids, Cottoids, Gobioids,* and many others); vaso-dentine (*Psammodus, Chimæroids, Pristis, Myliobates*); plici-dentine (*Lophius, Holoptychius, Lepidosteus oxyurus,* at the base of the teeth); labyrintho-dentine (*Lepidosteus platyrhinus, Bothriolepis*); and dendro-dentine (*Dendrodus*); besides the compound teeth of the *Scarus* and *Diodon*.

One structural modification may prevail in some teeth, another in other teeth of the same fish; and two or more modifications may be present in the same tooth, arising from changes in the process of calcification and a persistency of portions or processes of the primitive vascular pulp or matrix of the dentine.

The dense covering of the beak-like jaws of the Parrot-fishes (*Scari*), consists of a stratum of prismatic denticles, standing almost vertically to the external surface of the jaw-bone. An account of the structure and development of this peculiar armature of the jaws is abridged from my "Odontography" (pp. 112—116.), in the article PISCES (Vol. III. p. 979.). It is peculiarly adapted to the habits and exigencies of a tribe of fishes which browse upon the lithophytes that clothe, as with a richly tinted carpet, the bottom of the sea, just as the Ruminant quadrupeds crop the herbage of the dry land.

The irritable bodies of the gelatinous polypes which constitute the food of these fishes retract, when touched, into their star-shaped stony shells, and the Scari consequently require a dental apparatus strong enough to break off or scoop out these calcareous recesses. The jaws are, therefore, prominent, short, and stout, as shown in *fig.* 515. p. 979. Vol. III.; and the exposed portions of the premaxilliaries and premandibulars are encased by the complicated dental covering represented in *figs.* 515 and 516. Vol. III.

The polypes and their cells are reduced to a pulp by the action of the pharyngeal jaws

* The vaso-dentine of *Pristis* and *Myliobates* is like that of the teeth of the Cape Anteater (*Orycteropus*): the vaso-dentine of the Psammodonts resembles that which forms the base of the tooth of the Sloth and Megatherium: the vaso-dentine of Mammals differs from the osteo-dentine in the absence of the radiated "Purkinjian," cells.

† Wyman, American Journal of Natural Sciences, Oct. 1843. Cuvier has given an accurate view of the plaited structure of the base of the Wolf-fish's teeth in pl. 32, *fig.* 7. of his Leçons d'Anatomie Comparée, 1805; where it is described at the base of the osseous tubercle, which supports the true tooth.

‡ This remarkable structure attains its highest complication and forms the largest proportion of the tooth in the gigantic extinct labyrinthodont Batrachia, and from which, therefore, I have taken the illustrations of that complex modification of dental structure (*fig.* 552.). I had discovered in 1841 the more simple modification of this structure "at the base of the tooth in a few fishes" (Geol. Trans., 2d series, vol. vi., p. 507), but had not then seen so complex an example in that class as Dr. Wyman and M. Agassiz (Recherches sur les Poissons Fossiles, "Sauroides," 1843) subsequently described and figured, in teeth of the genus *Lepidosteus*.

and teeth, that close the posterior aperture of the mouth.

The superior dentigerous pharyngeals (*figs.* 558. and 565.) present the form of an elongated, vertical, inequilateral, triangular plate; the upper and posterior margin is sharp and concave; the upper and anterior margin forms a thickened articular surface, convex from side to side, and playing in a corresponding groove or concavity upon the base of the skull; the inferior boundary of the triangle is the longest, and also the broadest; it is convex in the antero-posterior direction, and flat from side to side. It is on this surface that the teeth are implanted, and in most species they form two rows; the outer one consisting of very small, the inner one of large dental plates, which are set nearly transversely across the lower surface of the pharyngeal bone, and are in close apposition, one behind the other: their internal angles are produced beyond the margin of the bone, and interlock with those of the adjoining bone when the pharyngeals are in their natural position; the smaller denticles of the outer row are set in the external interspaces of those of the inner row.

The single inferior pharyngeal bone consists principally of an oblong dentigerous plate, of the form represented in *fig.* 3, pl. 51, of my "Odontography;" its breadth somewhat exceeds that of the conjoined dentigerous surface of the pharyngeals above, and it is excavated to correspond with their convexity. This dentigerous plate is principally supported by a strong, slightly curved, transverse, osseous bar, the extremities of which expand into thick obtuse processes for the implantation of the triturating muscles. A longitudinal crest is continued downwards and forwards from the middle line of the inferior pharyngeal plate, anterior to the transverse bar, to which the protractor muscles are attached.

A longitudinal row of small oval teeth alternating with the large lamelliform teeth, like those of the superior pharyngeals, bounds the dentigerous plate on each side; the intermediate space is occupied exclusively by the larger lamelliform or wedge-shaped teeth, set vertically in the bone, and arranged transversely in alternate and pretty close set series.

The dental plates are developed in wide and deep cavities in the substance of the posterior part of the lower, and of the anterior part of the upper pharyngeal bones. Each denticle is developed in its proper capsule, which contains an enamel-forming pulp and a dentinal pulp, in close cohesion with each other and with the thin external capsule. The teeth exhibit progressive stages of formation as they approach the posterior part of the upper and the anterior part of the lower pharyngeal bones: as their formation advances to completion they become soldered together by ossification of their respective capsules into one compound tooth, which soon becomes anchylosed by ossification of the dentinal pulp to the pharyngeal bone itself.

The dentine of the pharyngeal teeth of the Scarus consists of calcigerous tubes and a clear intermediate substance. The calcigerous tubes average a diameter of $\frac{1}{20,000}$ of an inch, and are separated by interspaces equal to twice their own diameter. The course of these tubes is shown in *fig.* 558, *d.*, in which they are exposed by a vertical section through the middle of two of the superior denticles. They all, on leaving the pulp-cavity, form a curve with the convexity turned towards the base of the tooth, and then bend slightly in the opposite direction; the sigmoid curve being most marked in the calcigerous tubes at the base of the denticles, whilst those towards the apex become longer and straighter. Besides the primary curvatures exemplified in the figure, each calcigerous tube is minutely undulated; it dichotomises three or four times near its termination, sends off many fine lateral branches into the clear uniting substance, and finally terminates in a series of minute cells and inosculating loops at the line of junction with the enamel.

This substance (*fig.* 558, *e.*) is as thick as the dentine, and consists of a similar combination of minute tubes and a clear connecting substance. The tubes may be described as commencing from the pheripheral surface of the tooth to which they stand at right angles, and, having proceeded parallel to each other halfway towards the dentine, they then begin to divide and subdivide, the branches crossing each other obliquely, and finally terminating in the cellular boundary between the enamel and dentine.

The teeth which present this complex structure are successively developed at one extremity of the bone, in proportion as they are worn away at the other; not, however, as Cuvier describes, from behind forwards, in both upper and lower pharyngeal bones, but in opposite directions in the opposite bones, the course of succession being from before backwards in the upper, and from behind forwards in the lower pharyngeal bones. In the progress of the attrition to which they are subjected, the thin coat of cement resulting from the ossification of the capsule is first removed from the apex of the tooth, then the enamel constituting that apex, next the dentine, and, finally, the coarse central cellular bone, supporting the hollow wedge-shaped tooth; and thus is produced a triturating surface of four different substances of different degrees of density. The enamel, being the densest element, appears in the form of elliptical transverse ridges, inclosing the dentine and central bone; and external to the enamel is the cement which binds together the different denticles.

There is a close analogy between the dental mass of the Scarus and the complicated grinders of the elephant, both in form, structure, and in the reproduction of the component denticles in horizontal succession. But in the fish, the complexity of the triturating surface is greater than in the Mammal, since, from the mode in which the wedge-shaped denticles of the Scarus are implanted upon, and anchylosed to, the processes of the supporting bone, this likewise enters into the formation of the masticatory surface when the tooth is worn down to a certain point.

The proof of the efficacy of the complex masticatory apparatus above described is afforded by the contents of the alimentary canal of the Scari. Mr. Charles Darwin, the accomplished naturalist and geologist, who accompanied Captain Fitzroy, R. N., in the circumnavigatory voyage of the "Beagle," dissected several Parrot-fishes soon after they were caught, and found the intestines laden with nearly pure chalk, such being the nature of their excrements; whence he ranks these fishes among the geological agents to which is assigned the office of converting the skeletons of the Lithophytes into chalk.

Development.—As might have been anticipated from the discovery of the varied and predominating vascular organisation in the teeth of fishes, and the passage from non-vascular dentine to vascular dentine in the same tooth, the true law of the development of dentine "by centripetal metamorphosis and calcification of the cells of the pulp," was first definitely enunciated and illustrated from observations made on the development of the teeth of fishes.*

It is interesting to observe in this class the process arrested at each of the well-marked stages through which the development of a mammalian tooth passes. In all fishes the first step is the simple production of a soft vascular papilla from the free surface of the buccal membrane: in Sharks and Rays these papillæ do not proceed to sink into the substance of the gum, but are covered by caps of an opposite free fold of the buccal membrane; these caps do not contract any organic connection with the papilliform matrix, but, as this is converted into dental tissue, the tooth is gradually withdrawn from the extraneous protecting cap, to take its place and assume the erect position on the margin of the jaw (*fig.* 510, *b*, *a*, art. PISCES, Vol. III. p. 976.). Here, therefore, is represented the first and transitory "papillary" stage of dental development in Mammals; and the simple crescentic cartilaginous maxillary plate, with the open groove behind containing the germinal papillæ of the teeth, offers in the Shark a magnified representation of the earliest condition of the jaws and teeth in the human embryo.

In many fishes, e. g. *Lophius*, *Esox*, the dental papillæ become buried in the membrane from which they rise, and the surface to which their basis is attached becomes the bottom of a closed sac: but this sac does not become inclosed in the substance of the jaw; so that teeth at different stages of growth are brought away with the thick and soft gum, when it is stripped from the jaw-bone. The final fixation of teeth, so formed, is effected by the development of ligamentous fibres in the submucous tissue between the jaw and the base of the tooth, which fibres become the medium of connection between those parts, either as elastic ligaments, or by continuous ossification. Here, therefore, is represented the "follicular" stage of the development of a mammalian tooth; but the "eruptive" stage takes place without previous inclosure of the follicle and matrix in the substance of the jaw-bone.

In *Balistes*, *Scarus*, *Sphyræna*, the Sparoids, and many other fishes, the formation of the teeth presents all the usual stages which have been observed to succeed each other in the dentition of the higher *Vertebrata:* the papilla sinks into a follicle, becomes surrounded by a capsule, and is then included within a closed alveolus of the growing jaw (*fig.* 516. *c*, Vol. III. p. 979. art. PISCES), where the developement of the tooth takes place and is followed by the usual eruptive stages. A distinct enamel-pulp is developed from the inner surface of the capsule in *Balistes*, *Scarus*, *Sargus*, and *Chrysophrys*.

The most formidable dentition exhibited in the order of osseous fishes, is that which characterises the *Sphyræna*, and some extinct fishes allied to this predatory genus. In the great Barracuda of the southern shores of the United States (*Sphyræna Barracuda*, Cuv.), the lower jaw contains a single row of large, compressed, conical, sharp-pointed, and sharp-edged teeth, resembling the blades of lancets, but stronger at the base. The two anterior of these teeth are twice as long as the rest, but the posterior and serial teeth gradually increase in size towards the back part of the jaw; there are about twenty-four of these piercing and cutting teeth in each premandibular bone. They are opposed to a double row of similar teeth in the upper jaw, and fit into the interspace of these two rows when the mouth is closed. The outermost row is situated on the intermaxillary, the innermost on the palatine bones; there are no teeth on the vomer or superior maxillary bones. The two anterior teeth in each premaxillary bone equal the opposite pair in the lower jaw in size: the posterior teeth are serial, numerous, and of small size; the second of the two anterior large premaxillary teeth is placed on the inner side of the commencement of the row of small teeth, and is a little inclined backwards. The retaining power of all the large anterior teeth is increased by a slight posterior projection, similar to the barb of a fish-hook, but smaller. The palatine bones contain each nine or ten lancet-shaped teeth, somewhat larger than the posterior ones of the lower jaw. All these teeth afford good examples of the mode of attachment by implantation in sockets, which has been denied to exist in fishes.*

The loss or injury to which these destructive weapons are liable in the conflict which the *Sphyræna* wages with its living and

* In my Hunterian Lectures, delivered at the Royal College of Surgeons, May, 1839. See also, Compte Rendu de l'Académie des Sciences, Dec. 1839, p. 784.; and Odontography, Introduction, and part i. *passim.*

* Cuvier, Histoire Naturelle des Poissons, tom. i. p 492.

struggling prey, is repaired by an uninterrupted succession of new pulps and teeth. The existence of these is indicated by the foramina, which are situated immediately posterior to, or on the inner margin of, the sockets of the teeth in place; these foramina lead to alveoli of reserve, in which the crowns of the new teeth in different stages of development are loosely embedded. It is in this position of the germs of the teeth that the Sphyrænoid fishes, both recent and fossil, mainly differ, as to their dental characters, from the rest of the Scomberoid family, and proportionally approach the Sauroid type. The base or fang of the fully-developed tooth of the *Sphyræna* is anchylosed to the parietes of the socket in which it is inserted. The pressure of the crown of the new tooth excites absorption of the inner side of the base of the old, which thus finally loses the requisite strength of attachment; and its loss is followed by the absorption of the old socket, as in the higher animals.

It is interesting to observe that the alternate teeth are, in general, contemporaneously shed; so that the maxillary armour is always preserved in an effective state. The relative position of the new teeth to their predecessors, and their influence upon them, resembles, in the *Sphyræna,* some of the phenomena which will be described in the dentition of the crocodilian reptiles. To the crocodiles the present voracious fish also approximates in the alveolar lodgment of the teeth; but it manifests its ichthyic character in the anchylosis of the fully-developed teeth to their sockets, and still more strikingly in the intimate structure of the teeth.

In all fishes the teeth are shed and renewed, not once only, as in Mammals, but frequently, during the whole course of their lives. The maxillary dental plates of *Lepidosiren,* the cylindrical dental masses of the Chimæroid and Edaphodont fishes, and the rostral teeth of *Pristis* (if these modified dermal spines may be so called) are, perhaps, the sole examples of "permanent teeth" to be met with in the whole class.

When the teeth are developed in alveolar cavities, they are usually succeeded by others in the vertical direction, as in the pharyngeal bones of the Labroids (*fig.* 513., art. PISCES, Vol. III. p. 978.); but sometimes they follow one after the other, side by side, as in the Scaroids (PISCES, *fig.* 516. *c,* p. 979.). The successional teeth owe the origin of their matrix to the budding out from the capsule of their predecessors of a cæcal process, in which the papillary rudiment of the dentinal pulp is developed according to the laws explained in the Introduction to my "Odontography," and the article TOOTH. But, in the great majority of fishes, the germs of the new teeth are developed, like those of the old, from the free surface of the buccal membrane throughout the entire period of succession; a circumstance peculiar to the present class. The Angler, the Pike, and most of our common fishes, illustrate this mode of dental reproduction; it is very conspicuous in the cartilaginous fishes, in which the whole phalanx of their numerous teeth is ever marching slowly forwards in rotatory progress over the alveolar border of the jaw, the teeth being successively cast off as they reach the outer margin, and new teeth rising from the mucous membrane behind the rear rank of the phalanx.

This endless succession and decadence of the teeth, together with the vast numbers in which they often coexist in the same fish, illustrate the law of Vegetative or Irrelative Repetition, as it manifests itself on the first introduction of new organs in the animal kingdom, under which light we must view the above-described organised and calcified preparatory instruments of digestion in the lowest class of the vertebrate series.

At the extreme limit of the class of fishes, and connecting that class with the reptiles, stands the very remarkable genus, the dental system of which is figured in cut 560. This consists of two small, slender, conical, sharp-pointed, and slightly recurved teeth, which project downwards from the nasal bone (*c*), and of strong trenchant dental plates anchylosed with the alveolar border of the upper (*a*) and lower (*b*) jaws, in each of which the plate is divided at the middle, or symphysial line, so as to form two distinct lateral teeth.

The office of the two laniariform teeth is to pierce and retain the nutritive substance or prey which is afterwards divided and comminuted by the strong maxillary dental plates.

The upper pair of these plates is supported by the anterior part of a strong arch of bone, which combines the characters of the superior maxillary, palatine, and pterygoid bones; the superior maxillary is represented by the median and anterior bar, passing in front of the dental plate of the lower jaw when the mouth is shut, terminating on each side in a process which projects outwards and backwards, as in *fig.* 560., *a.*, on each side of the anterior part of the arch; the palatine portion constitutes the median part of the roof of the mouth behind the foregoing; the pterygoid portion is indicated by its fulfilling the usual function of an abutment extended between the palatine portion of the upper jaw and the articular pedicle of the lower jaw; the upper dental plates are confined to the first two parts of the arch (maxillary and palatine), and do not extend upon the pterygoid portion; the lower dental plates (*b*) are anchylosed to the premandibular bone. Viewing the upper pair of plates as a single tooth, it may be described as indented at its outer surface by five vertical angular notches, penetrating inwards through half the breadth of the supporting bone, and dividing the plate into six angular processes, which, from the direction and varying form and breadth of the entering notches, radiate from the posterior part of the median line or division of the tooth. The inferior dental plate is similarly notched on its outer side, but the proportions of the angular indentations are such, that they receive all the processes of the upper dental plate when the mouth is shut, whilst only the four anterior processes are reciprocally received into the notches of the upper dental plate, this, with the supporting arch, being anterior to the lower plate,—a position which is decisive in favour of its maxillary character, and against its homology with the vomer.

The dental plate consists, as in the Cod and *Sphyræna*, of a central mass of coarse osseous substance, traversed by large and nearly parallel medullary canals, and an external sheath of very hard "vitro-dentine." The medullary canals are continued from a coarse reticulation of similar but wider canals in the substance of the supporting bone, and advance forwards, nearly parallel with each other and with the plane of the upper surface of the tooth; they anastomose together by short, curved, transverse canals, which intercept spaces increasing in length as the canals recede from the osseous basis. The canals themselves diminish in size in the same ratio; and when they have arrived near the dense outer layer, their divisions and inosculations become again more frequent, the peripheral loops forming a well-marked line of demarcation between the coarse-tubed and the fine-tubed dentine. The interspaces of the medullary canals are occupied by a clear substance, and by moss-like reticulations of fine dentinal tubes, which appear to be more sparing in number than in the teeth of the *Sphyræna* or Shark. The dentinal tubes of the vitro-dentine run nearly parallel to each other, and vertically to the external surface of the dental plate through about two-thirds of the thickness of that tissue; they then bend and cross each other in a manner very similar to those of the vitro-dentine in the teeth of the *Lepidotus*, *Phyllodus*, &c.*

In the process of attrition this external dense substance is worn away from the upper surface of the dental processes in the lower jaw, exposing the softer vaso-dentinal substance of the tooth; in this state the dental plate offers an analogy to the incisors of the Rodents, a posterior softer substance being sheathed by an anterior denser layer; and an external sharp edge is similarly kept up by the unequal wearing away of the two substances. The progressive waste at the upper surface of the dental plate would appear to be met by a corresponding additon of new material to its lower part.

In the structure here presented we have a condition of the dentine which has hitherto been met with only in the class of fishes.

The test of the affinities of the present paradoxical genus, afforded by the microscopic examination of the teeth, gives additional confirmation to the view to which I have been led, from arguments drawn from the rest of its organisation, that the *Lepidosiren* is in every essential point a member of the class of fishes.†

* See Odontography, pp. 70. 166, pl. 59, *fig.* 4.

† Linnean Transactions, vol. xviii. 1839. p. 350. That the large size, or elliptical form of its blood-discs should outweigh the cumulative evidence establishing the piscine nature of the *Lepidosiren* could only be surmised by those who are ignorant of the variation in size and shape which the blood-discs present in the class of fishes, and the consequent unimportance of those particles as a character of the class. As well might the *Petromyzon* be deemed a mammal because its blood-discs are circular and comparatively small, as the *Lepidosiren* be held to be a Batrachian because its blood-discs are elliptical and comparatively large.

Dental System of Reptiles.

If we compare the dental system of the foregoing Batrachoid fish with that in the true *Batrachia*, it is only to the larval state of the Anourans that an analogy can be found; the tadpole of the frog having its maxilla and mandibula each sheathed with a single and continuous horny dental trenchant covering. Were this sheath actually dentinal in tissue and united to the jaw-bone, the resemblance to the *Lepidosiren* would be closer; but in point of fact the analogy is very remote; the horny beak of the tadpole is never calcified or anchylosed, but is shed during the progress of the metamorphosis.* The Siren alone, among the larval-like perennibranchiate reptiles, retains the sheath upon the extremity of the upper and lower jaws; it consists of a firm albuminous tissue, and becomes harder than horn. But these trenchant mandibles, which play upon one another like the blades of a pair of curved scissors, are associated with numerous small but distinct true teeth, which are grouped together to form a rasp-like surface on each half of the divided vomer, and which beset the alveolar border of the splenial element of the mandible below.

In the class *Reptilia*, the whole order of *Chelonia* is edentulous, as well as the whole family of Toads (*Bufonidæ*) in the order *Batrachia;* certain extinct genera of Saurians were likewise edentulous, *e.g.* the remarkable "*Rhynchosaurus*" of the new red sandstone of Shropshire, and some of the extinct Saurians of South Africa.

In the tortoises and turtles the jaws are covered by a sheath of horn, which in some species is of considerable thickness and very dense; its working surface is trenchant in the carnivorous species, but variously sculptured, and adapted for both cutting and bruising in the vegetable feeders; it may be said that the transitory condition of the mandibles of the Batrachian larvæ is here persistent.

The development of the continuous horny maxillary sheath commences, as in the parrot tribe, from a series of distinct papillæ, which sink into alveolar cavities, regularly arranged (in *Trionyx*) along the margins of the upper and lower jaw-bones: these alveoli are indicated by the persistence of vascular canals long after the originally separate tooth-like cones have become confluent, and the horny sheath completed.

The teeth of the dentigerous Saurian,

* The large dental plates of *Lepidosiren* have their nearest homologues in those of the extinct fish called *Ceratodus* (Odontography, pl. 22, *fig.* 2.).

Ophidian, and Batrachian reptiles, are, for the most part, simple and adapted for seizing and holding, but not for dividing or masticating their food. The Siren alone combines true teeth with a horny maxillary trenchant sheath, like that of the Chelonian reptiles.

With respect to *number*, in no existing reptile are the teeth reduced so low as in certain mammals and fishes; nor, on the other hand, are they ever so multiplied as in many of the latter class. The extinct Dicynodont reptiles of South Africa had but two teeth, which were long tusks implanted in the upper jaw.* Some species of *Amphisbœna* (*A. alba*), with fifteen teeth in the upper jaw and fourteen in the lower jaw, and certain Monitors (*Varanus*), with sixteen teeth in the upper and fourteen in the lower jaw, afford examples of the smallest number of teeth amongst existing reptiles; and certain Batrachians, with teeth "en cardes" at the roof of the mouth, or which have upwards of eighty teeth in each lateral maxillary series, present the largest number. It is rarely that the number of the teeth is fixed and determinate in any reptile so as to be characteristic of the species, and still more rarely have the individual teeth such characters as to be determined homologically from one species to another.

With respect to *situation*, the teeth may be present on the jaws only, *i.e.* the maxillary, premaxillary, and mandibular bones, as in the crocodiles and many lizards: or upon the jaws and roof of the mouth; and here either upon the pterygoid bones, as in the Iguana and Mosasaur, or upon both palatine and pterygoid bones, as in most serpents, or upon the vomer, as in most Batrachians, or upon both vomerine and pterygoid bones, as in the Axolote; or upon the vomerine and sphenoid bones, as in the *Salamandra glutinosa*, Maclure. With respect to the marginal or jaw teeth, these may be absent in the intermaxillary bones, as in many serpents; or they may be present in the upper and not in the lower jaw, as in most frogs; or in both upper and lower jaws, as in the tailed Batrachians; and among these they may be supported, upon the lower jaw, by the premandibular or dentary piece, as in the Salamanders, Menopome, Amphiume, Proteus; or upon the splenial piece, as in the Siren; or upon both splenial and premandibular bones, as in the Axolotl. The palatine and pterygoid teeth may, in the Batrachians, be arranged in several rows, like the "dents en cardes" of fishes. The sphenoid and splenial teeth are always so arranged in the few species that possess them. The intermaxillary, maxillary, and premandibular teeth are uniserial, or in one row, with the exception of the Cæcilia and the extinct Labyrinthodonts, which have a double row of teeth at the anterior part of the lower jaw.

The teeth of reptiles, with few exceptions, present a simple conical *form*, with the crown more or less curved, and the apex more or less acute. The cone varies in length and thickness; its transverse section is sometimes circular, but more commonly elliptical or oval, and this modification of the cone may be traced through every gradation, from the thick, round, canine-like tooth of the crocodile, to the sabre-shaped fang of the Varanus, the Megalosaur, and the Cladeiodon.* Sometimes, as in the fully formed teeth of the Megalosaur, one of the margins of the compressed crown of the tooth is trenchant, sometimes both are so; and these may be simply sharp-edged, as in the Varanus of Timor, or finely serrated, as in the great Varanus, the Cladeiodon, and the Megalosaur.†

The outer surface of the crown of the tooth is usually smooth; it may be polished, as in the Leiodon, or impressed with fine lines, as in the Labyrinthodon (*fig.* 551.), or raised into many narrow ridges, as in the Pleiosaur and Polyptychodon, or broken by a few broad ridges, as in the Iguanodon (*fig.* 571.), or grooved by a single longitudinal furrow, as in some serpents (*fig.* 569, A).‡

The cone is longest and its summit sharpest in the serpents: from these may be traced, chiefly in the lizard tribe, a progressive shortening, expansion of the base, and blunting of the apex of the tooth, until the cone is reduced to a hemispherical tubercle, or plate, as in the Thorictes and Cyclodus (*fig.* 570.).

In the Pleiosaur the dental cone is three-sided, with one of the angles rounded off. The posterior subcompressed teeth of the alligator (*fig.* 573.) present a new modification of form; here they terminate in a mammillate summit, supported by a slightly constricted neck. In the tooth of the Hylœosaur the expanded summit is flattened, bent, and spear-shaped, with the edges blunted. But the expansion of the crown is greatest in the subcompressed teeth of the extinct *Cardiodon* and the existing Iguanas, the teeth of which are farther complicated by having the margins notched. The great Iguanodon had the crown of the tooth expanded both in length and breadth, and combining marginal dentations with longitudinal ridges: this tooth (*fig.* 571.) presents the most complicated external form as yet discovered in the class of reptiles.

In no reptiles does the base of the tooth ever branch into fangs.

Attachment.—As a general rule, the teeth of reptiles are anchylosed to the bone which supports them. When they continue distinct, they may be lodged either in a continuous groove, as in the Ichthyosaur §, or in separate sockets, as in the Plesiosaur and Crocodilians (*fig.* 573.). The base of the tooth is anchylosed to the walls of a moderately deep socket in the extinct Megalosaur and Theocodon. In the Labyrinthodonts and Cæciliæ, among the Bratrachians; in most Ophidians; and in the Geckos, Agamians, and Varanians, among the Saurians, the base of the tooth is

‡ Ib. pl. 65; vol. iv., *figs.* 209, 210.
§ Ib. pl. 13, *fig.* 9.

imbedded in a shallow socket, and is confluent therewith.

In the Scincoidians, the Safeguards (*Tejus*), in most Iguanians, in the Chameleons and most other Lacertian reptiles, the tooth is anchylosed by an oblique surface extending from the base more or less upon the outer side of the crown to an external alveolar plate of bone*, the inner alveolar plate not being developed. In the frogs the teeth are similarly but less firmly attached to an external parapet of bone. The lizards which have their teeth thus attached to the side of the jaw are termed Pleurodonts. In a few Iguanians, as the Istiures, the teeth appear to be soldered to the margins of the jaws, these have been termed "Acrodonts." In some large extinct Lacertians, *e. g.* the Mosasaur and Leiodon, the tooth is fixed upon a raised conical process of bone, as shown in my "Odontography," Plate 68. *fig.* 1., and Plate 72. *fig.* 2.

These modifications of the attachment of the teeth of reptiles are closely adapted to the destined application of those instruments, and relate to the habits and food of the species; we may likewise perceive that they offer a close analogy to some of the transitory conditions of the human teeth. There is a period, for example †, when the primitive dental papillæ are not defended by either an outer or an inner alveolar process, any more than their calcified homologues which are confluent with the margin of the jaw in the *Rhynchocephalus*.‡ There is another stage §, in which the groove containing the dental germs is defended by a single external cartilaginous alveolar ridge; this condition is permanently typified in the *Cyclodus* (*fig.* 570.) and most existing lizards. Next there is developed in the human embryo an internal alveolar plate, and the sacs and pulps of the teeth sink into a deep but continuous groove, in which traces of transverse partitions soon make their appearance; in the ancient Ichthyosaur the relation of the jaws to the teeth never advanced beyond this stage.

Finally, the dental groove is divided by complete partitions ||, and a separate socket is formed for each tooth; and this stage of developement is attained in the highest organised reptiles, *e. g.* the crocodiles (*fig.* 573.).

Substance. — This may be four-fold, and a single tooth may be composed of dentine, cement, enamel, and bone; but the dentine and cement are present in the teeth of all reptiles.

In the Batrachians and Ophidians a thin layer of cement invests the central body of dentine, and, as usual, follows any inflections or sinuosities that may characterise the dentine. Besides the outer coat of cement, which is thickest at the base of the teeth, a generally thin coat of enamel defends the crown of the tooth in most Saurians, and the last remains of the pulp are not unfrequently converted into a coarse bone, both in the teeth which are anchylosed to the jaw, and in some teeth, as those of the Ichthyosaur, which remain free. The only modification of the dentine, which could at all entitle it to be regarded in the light of a new or distinct substance, is that which is peculiar in the present class to the teeth of the Iguanodon, and which will be described in the following section.

Structure. — The varieties of dental structure are few in the reptiles as compared with either fishes or mammals, and its most complicated condition arises from interblending of the dentinal and other substances rather than from modifications of the tissues themselves. In the teeth of most reptiles the intimate structure of the dentine corresponds with that which has been described as the type of the tissue, *e.g.* the hard or unvascular dentine, and which is the prevailing modification in Mammalia, viz., the radiation of a system of minute plasmatic tubes from a single pulp-cavity, at right angles to the external surface of the tooth. The most essential modification of this structure is the intermingling of cylindrical processes of the pulp-cavity in the form of medullary canals, with the finer tubular structure.* Another modification is that in which the dentine maintains its normal structure, but is folded inwardly upon itself, so as to produce a deep longitudinal indentation on one side of the tooth; it is the expansion of the bottom of such a longitudinal deep fold that forms the central canal of the venom-fang of the serpent; but a glance at *fig.* 568. will show that, notwithstanding the singularly modified disposition of the dentine (*b*), its structure remains unaltered; and although the pulp-cavity (*p*) is reduced to the form of a crescentic fissure, the dentinal tubes continue to radiate from it according to the usual law. By a similar inflection of many vertical longitudinal folds of the external cement and external surface of the tooth at regular intervals around the entire circumference of the tooth, and by a corresponding extension of radiated processes of the pulp-cavity and dentine into the interspaces of such inflected and converging folds, a modification of dental structure is established in certain extinct reptiles, which, by the various sinuosities of the interblended folds of cement and processes of dentine, with the partial dilatations of the radiated pulp-cavity, produces the complicated structure which is described at p. 868. and figured in cut 552. But this complication is nevertheless referable to a modification of form or arrangement of the dental tissues, rather than of the structure of the tissues themselves: the calcigerous tubes in each sinuous lobe of dentine, in the most

complex tooth of the Labyrinthodon, exhibit the same general disposition and course as in the fang of the serpent and in the still more simple tooth of the Saurian.

Development.—The teeth of reptiles are never completed, as in certain fishes, at the first or papillary stage; but the pulp sinks into a follicle, and becomes inclosed by a capsule; and in certain reptiles this becomes more or less surrounded by bone; but the process of development never offers the eruptive stage, in the sense in which this is usually understood, as signifying the extrication of the young tooth from a closed alveolus.

The completion of a tooth, with the extinct exception of the Dicynodont Reptiles, is soon followed by preparation for its removal and succession: the faculty of developing new tooth-germs seems to be unlimited in the present class, and the phenomena of dental decadence and replacement are manifested at every period of life; the number of teeth is generally the same in each successive series, and the difference of size presented by the teeth of different and distant series is considerable.

The new germ is always developed, in the first instance, at the side of the base of the old tooth, never in the cavity of the base; the crocodiles form no exception to this rule. The poison-fangs of serpents succeed each other from behind forwards; in almost every other instance the germ of the successional tooth is developed at the inner side of the base of its predecessor. In the frog the dental germ makes its appearance in the form of a papilla developed from the bottom and towards the outer side of a small fissure in the mucous membrane or gum that fills up the shallow groove at the inner side of the alveolar parapet and its adherent teeth: the papilla is soon enveloped by a capsular process of the surrounding membrane: there is a small enamel pulp developed from the capsule opposite the apex of the tooth; the deposition of the earthy salts in this mould is accompanied by ossification of the capsule, which afterwards proceeds *pari passu* with the calcification of the dentinal papilla or pulp; so that, with the exception of its base, the surface of the uncalcified part of the pulp alone remains normally unadherent to the capsule.

As the tooth acquires hardness and size, it presses against the base of the contiguous attached tooth, causes a progressive absorption of that part, and finally undermines, displaces, and replaces its predecessor. The number of nascent matrices of the successional teeth is so great in the frog, and they are crowded so close together, that it is not unusual to find the capsules of contiguous tooth-germs becoming adherent together, as their ossification proceeds. After a brief maceration, the soft gum may be stripped from the shallow alveolar depression, and the younger tooth-germs in different stages of growth are brought away with it.

The mode of development of the teeth of serpents does not differ essentially from that of the teeth of the Batrachian above described except in the relation of the papillæ of the successional poison-fangs to the branch of the poison-duct that traverses the cavity of the loose mucous gum in which they are developed.

Batrachian modifications.—Some of the peculiarities of the dentition of the Batrachians have already been noticed, as in the comparison of the *Siren* with the *Lepidosiren*, in which the true amphibian was shown to have numerous teeth on the palate and lower jaw.*

The piscine character of rasp-like teeth aggregated in numerous series, is manifested also in the Axolotl †, upon the palatal region of the mouth, and upon the splenial or opercular element of the lower jaw; but the superior maxillary bones are here developed, and also support teeth. The premandibular and the premaxillary bones, instead of preserving the larval condition of the horny sheath, have their alveolar border armed with a single row of small, equal, fine and sharp-pointed denticles, which are continued above, along the maxillaries; thus establishing the commencement of the ordinary Batrachian condition of the marginal teeth of the buccal cavity. The dentigerous bones of the palate consist of two plates on each side, as in the *Siren;* the anterior pair, or vomerine bones, converge and meet at their anterior extremities; the minute denticles which they support are arranged quincuncially; the posterior pair of bones are continued backwards according to the usual disposition of the pterygoids, to abut against the tympanic bones; the denticles are confined to the anterior part of their oral surface, and resemble in their arrangement and anchylosed attachment those of the vomerine series, of which they form the posterior termination.

The frogs (*Rana*) ‡ have no teeth on the lower jaw; but in some species the alveolar edge of this bone is finely notched or dentated, as in the horned frogs (*Ceratophrys*). The intermaxillary and maxillary bones support a long, close-set, single series of small, conical, hollow teeth, of which the apices only project beyond the external alveolar ridge to which they are attached. A short transverse row of similar but smaller teeth extends along the posterior border of each vomer, except in the slender-armed frogs (*Leptobrachium*), and in some of the tree frogs (e. g. *Euchnemis*), in which the roof of the mouth is edentulous.

Amongst the most extraordinary examples of extinct reptiles are those which are characterised by the labyrinthic modification of the dental structure above described, and which with some affinities to Saurians, combine characters which are essentially those of the order *Batrachia.* I have ascertained by fossil portions of the upper jaw of the *Labyrinthodon leptognathus* that the maxillary or facial division of the skull was broad, much depressed, and flattened, resembling the skull of the

* Odontography, pl. 62, *figs.* 5 & 6
† Ib. pl. 62, *fig.* 4.
‡ Ib. pl. 62, *fig.* 10.

gigantic Salamander and of the Alligator; and the outer surface of the bones was strongly sculptured, as in the Crocodilian family, but of a relatively larger and coarser pattern. The upper jaw contains a single row of small teeth, about sixty in number, anterior to which are three or four large conical tusks. The bases of the serial teeth project directly from the outer wall of the shallow socket, there being no alveolar ridge external to it. The second large anterior tusk is three times the size of the first of the serial teeth, and the size of these teeth gradually diminishes as they are placed further back; the length of the common-sized teeth being about two lines, and the greatest breadth one-third of a line. The apical two-thirds of each tooth is smooth, but the basal third is fluted and anchylosed to the outer wall of the socket. The osseous roof of the mouth is principally composed of a pair of broad and flat bones, homologous with the divided vomer in *Batrachia*, but of much greater relative extent, approaching, in this respect, those of the Menopome, and defending the mouth with a more extensive roof of bone than exists in any Lacertian reptile; physiologically, therefore, the *Labyrinthodon*, in this part of its structure, comes nearest to the Crocodile; but the structure itself, morphologically, is essentially Batrachian.* In the Menopome† and gigantic Salamander, a row of small teeth extends transversely across the anterior extremity of the vomerine bones; and the occurrence in the *Labyrinthodon* of a similar row, consisting in each palatine bone of three median small teeth and two outer larger ones, marks most strongly its Batrachian nature; and from the outermost tooth a longitudinal row of small and equal-sized teeth is continued backward along the exterior margin of the palatine bone. The whole of this series of palatal teeth is nearly concentric with the maxillary teeth.

In Lacertine reptiles the examples of a row of palatal teeth are rare, and, when present, it is short, and situated towards the back of the palate, upon the pterygoid bones, as in the Iguana and Mosasaur.‡ In Batrachians the most common disposition of the palatal teeth is a transverse row placed at the anterior part of the divided vomer, as in Frogs, the Menopome and gigantic Salamander, and at the posterior part in certain toads. In the Amphiume, on the contrary, the palatal teeth form a nearly longitudinal series along the outer margin of the palatine bones. The *Labyrinthodon* combines both these dispositions of the palatal teeth. The lower jaw, like the upper, contains a series of small teeth, with a few larger tusks anterior to them, the serial teeth are long and slender, gradually diminishing in size towards the anterior portion of the jaw; the largest fossil portion which I have obtained presents a linear series of not less than fifty sockets, placed alternately, one nearer the inner, the next nearer the outer side of the jaw. The sockets of the teeth are shallower than in the upper jaw; the outer wall is more developed than the inner, and the anchylosed bases of the teeth more nearly resemble, in their oblique position, those of existing *Batrachia*. With regard to the modification of the microscopic structure of the teeth, I may observe that, between the apex and the part where the inflected vertical folds of the cement commence, the tooth resembles, in the simplicity of its intimate structure, that of the entire tooth of ordinary *Batrachia* and most reptiles; and in the lower or basal half of the tooth the labyrinthic structure above described commences, and gradually increases in complexity.

* Odontography, pl. 63. A, *fig.* 3.
† Ib. pl. 62. *figs.* 1 & 2.
‡ Ib. pl. 68.

In the genus *Deirodon**, the teeth of the ordinary bones of the mouth are so small as to be scarcely perceptible; and they appear to be soon lost, so that it has been described as edentulous, and has been called "Anodon." An acquaintance with the habits and food of this species has shown how admirably this apparent defect is adapted to its well-being. Its business is to restrain the undue increase of the smaller birds by devouring their eggs. Now if the teeth had existed of the ordinary form and proportions in the maxillary and palatal regions, the egg would have been broken as soon as it was seized, and much of the nutritious contents would have escaped from the lipless mouth of the snake in the act of deglutition; but, owing to the almost edentulous state of the jaws, the egg glides along the expanded opening unbroken; and it is not until it has reached the gullet, and the closed mouth prevents any escape of the nutritious matter, that the egg becomes exposed to instruments adapted for its perforation. These instruments consist of the inferior spinous pocessess (hypapophyses) of the seven or eight posterior cervical vertebræ, the extremities of which are capped by a layer of hard cement, and penetrate the dorsal parietes of the œsophagus. They may be readily seen, even in very small subjects, in the interior of that tube, in which their points are directed backwards. The shell being sawed open longitudinally by these vertebral teeth, the egg is crushed by the contractions of the gullet, and is carried to the stomach, where the shell is no doubt soon dissolved by the acid gastric juice.

In the *Boa Constrictor*, the teeth are slender, conical, suddenly bent backwards and inwards above their base of attachment; the crown is straight or very slightly curved, *e. g.* in the posterior teeth. The intermaxillary bone supports four small teeth; each maxillary bone has eight much larger ones, which gradually decrease in size as they are placed further back. There are eight or nine teeth of similar size and proportions in each premandibular bone. These teeth

* The *Coluber scaber* of Linnæus; an arboreal serpent of South Africa.

are separated by wide intervals, from which other teeth, similar to those in place, have been detached. The base of each of the above teeth is extended transversely, compressed antero-posteriorly, and anchylosed to a shallow alveolus, extending obliquely across the shallower alveolar groove. An affinity to the lizard tribes is manifested by the greater development of the outer, as compared with the inner wall of the alveolar furrow.

The palatine teeth, of which there are three or four in each palatal bone, are as large as the superior maxillary, and are similarly attached. The pterygoid teeth, five or six in number, which complete the internal dental series on the roof of the mouth, are of smaller size, and gradually diminish as they recede backwards. In the interspaces of the fixed teeth in both these bones, the places of attachment of the shed teeth are always visible; so that the dental formula, if it included the vacated with the occupied sockets, would express a greater number of teeth than are ever in place and use at the same time.* In the smaller species of Boa, the intermaxillary bone is edentulous.

The *Colubers*, like other true serpents, have two longitudinal rows of teeth on the roof of the mouth, extending along the palatines and pterygoids. The genus *Oligodon* appears to form the sole exception to this rule. In the *Dryinus nasutus*, a few small teeth are present on the ecto-pterygoid as well as on the pterygoid.

In certain genera of non-poisonous serpents, as *Dryophis*, *Dipsas*, and *Bucephalus*, in which the superior maxillary teeth increase in size towards the posterior part of the bone, the large terminal teeth of the series are traversed along their anterior and convex side by a longitudinal groove. In the *Bucephalus capensis*, the two or three posterior maxillary teeth present this structure, and are much larger than the anterior teeth, or those of the palatine and premandibular series. They add materially, therefore, to the power of retaining the prey, and may conduct into the wounds which they inflict an acrid saliva; but they are not in connection with the duct of an express poison-gland. The long-grooved fangs are either firmly fixed to the maxillary bones, or are slightly moveable, according to their period of growth. They are concealed by a sheath of thick and soft gum, and their points are directed backwards. The sheath always contains loose recumbent grooved teeth, ready to succeed those in place.

In most of the *Colubri*, each maxillary and premandibular bone includes from twenty to twenty-five teeth. They are less numerous in the genera *Tortrix* and *Homalopsis*, and are reduced to a still smaller number in the poisonous serpents, in the typical genera of which the short maxillary bone supports only a single perforated fang.

* Odontography, pl. 65, *figs.* 6 & 7.

Poisonous Serpents. — The transition to these serpents, which was begun in the *Bucephali* and allied genera with grooved maxillary teeth, is completed by the poisonous serpents of the genera *Pelamis*, *Hydrophis*, *Elaps*, *Bongarus*, and *Hamadryas*.

The superior maxillary bone diminishes in length with the decreasing number of teeth which it supports. The ecto-pterygoid bone elongates in the same ratio, so as to retain its position as an abutment against the shortened maxillary, and the muscles implanted into this external pterygoid bone communicate through it to the maxillary bone the hinge-like movements backwards and forwards upon the ginglymoid articulations connecting that bone with the prefrontal and palatine bones. As the fully-developed poison-fangs are attached by the same firm basal anchylosis to maxillary sockets, which forms the characteristic mode of attachment of the simple or solid teeth, they necessarily follow all the movements of the superior maxillary bone. When the external pterygoid is retracted, the superior maxillary rotates backwards, and the poison-fang is concealed in the lax mucous gum, with its point turned backwards. When the muscles draw forward the external pterygoid, the superior maxillary bone is pushed forwards, and the recumbent fang withdrawn from its concealment and erected.

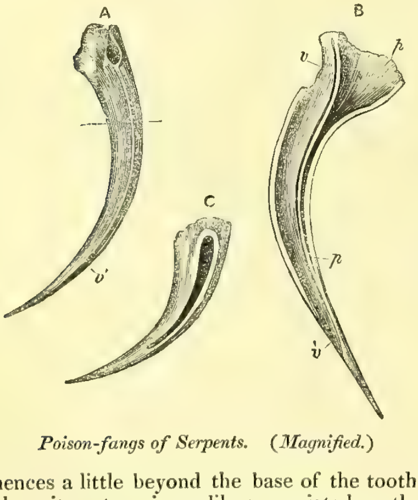
In this power of changing the direction of a large tooth, so that it may not impede the passage of food through the mouth, we may perceive an analogy between the viper and the Lophius; but in the fish the movement is confined to the tooth alone, and is dependent on the mere physical property of the elastic medium of attachment; in the serpent the tooth has no independent motion, but rotates with the jaw, whose movements are governed by muscular actions. In the fish the great teeth are erect, except when pressed down by some extraneous force. In the serpent the habitual position of the fang is the recumbent one, and its erection takes place only when the envenomed blow is to be struck.

A true idea of the structure of a poison-fang will be formed by supposing the crown of a simple tooth, as that of a boa, to be pressed flat, and its edges to be then bent towards each other, and soldered together so as to form a hollow cylinder, or rather cone, open at both ends. The flattening of the fang and its inflection around the poison-duct commences immediately above the base, and the suture of the inflected margins runs along the anterior and convex side of the recurved fang, as shown in *fig.* 567, A.: the poison-canal is thus in front of the pulp-cavity, as shown in the longitudinal section of the fang B. The basal aperture of the poison-canal v is oblique, and its opposite outlet v' is still more so, presenting the form of a narrow elliptical longitudinal fissure terminating at a short distance from the apex of the fang. The relative position of the two apertures of the poison-canal is shown in the figure of the fang of the large Cobra in my "Odontography" (pl. 65. *fig.* 9., and in Vol. IV. p. 290. *fig.* 210., art. Reptilia), where a fine hair is represented as passing through the poison-canal.

The poison-glands occupy the sides of the posterior half of the head; each gland consists of a number of elongated narrow lobes, extending from the main duct, which runs along the lower border of the gland upwards and slightly backwards: each lobe gives off lobules throughout its extent, thus presenting a pinnatifid structure; and each lobule is subdivided into smaller secerning cæca, which constitute the ultimate structure of the gland. The whole gland is surrounded by a double aponeurotic capsule, of which the outermost and strongest layer is in connection with the muscles by whose contraction the several cæca and lobes of the gland are compressed and emptied of their secretion. This is then conveyed by the duct (see Reptilia, Vol. IV. p. 291., *fig.* 211. *e*) to the basal aperture of the poison-canal of the fang *f.* We may suppose, that as the analogous lachrymal and salivary glands in other animals are most active during particular emotions, so the rage which stimulates the venom-snake to use its deadly weapon must be accompanied with an increased secretion and great distension of the poison-glands; and as the action of the compressing muscles is contemporaneous with the blow by which the serpent inflicts the wound, the poison is at the same moment injected with force into the wound from the apical outlet of the perforated fang.

The duct which conveys the poison, although it runs through the centre of a great part of the tooth, is really on the outside of the tooth, the canal in which it is lodged and protected being formed by a longitudinal inflection of the dentinal parietes of the pulp-cavity. This inflection com-

Fig. 567.

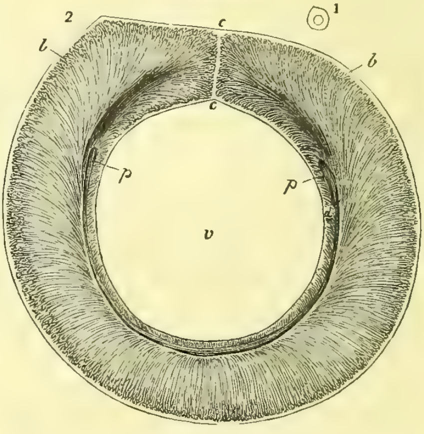


Poison-fangs of Serpents. (*Magnified.*)

mences a little beyond the base of the tooth, where its nature is readily appreciated, as the poison-duct there rests in a slight groove or longitudinal indentation on the convex side of the fang; as it proceeds it sinks deeper into the substance of the tooth, and the sides of the groove meet and seem to coalesce, so that the trace of the inflected fold ceases, in some species, to be perceptible to the naked eye; and the fang appears, as it is commonly described, to be perforated by the duct of the poison-gland. In the *Hydrophis* the groove remains permanently open, as in *fig* 567. c.

From the real nature of the poison-canal it follows that the transverse section of the tooth varies in form in different parts of the tooth; at the base it is oblong, with a large pulp-cavity of a corresponding form, with an entering notch at the anterior surface; farther on the transverse section presents the form of a horse-shoe, and the pulp-cavity that of a crescent, the horns of which extend into the sides of the deep cavity of the poison-fang: a little beyond this part the section of the tooth itself is crescentic, with the horns obtuse and in contact, so as to circumscribe the poison-canal; and along the whole of the middle four-sixths of the tooth, the section, of which a magnified view is given in *fig.* 568.,

Fig. 568.



Section of poison-fang of Serpent. (*Magnified.*)

shows the dentine of the fang inclosing the poison-canal, and having its own centre or pulp-canal (p, p), in the form of a crescentic fissure, situated close to the concave border of the inflected surface of the tooth. The pulp-cavity disappears, and the poison-canal again resumes the form of a groove near the apex of the fang, and terminates on the anterior surface in an elongated fissure.

The venom-fangs of the viper, rattle-snake, and the *Fer-de-lance* are coated only with a thin layer of a subtransparent and minutely cellular cement. The disposition of the dentinal tubes is obedient to the general law of verticality to the external surface of the tooth; it is represented as seen in the transverse section from the middle of the fang in *fig.* 568. Since the inflected surface of the tooth can be exposed to no other pressure than that of the turgescent duct with which it is in contact, the tubes which proceed to the surface *d*, while maintaining their normal relation of the right angle to it, are extremely short; and the layer of dentine separating the poison-tube from the pulp-cavity is proportionally thin. The calcigerous tubes that radiate from the opposite side of the pulp-cavity to the exposed surface *b* of the tooth are disproportionally long.

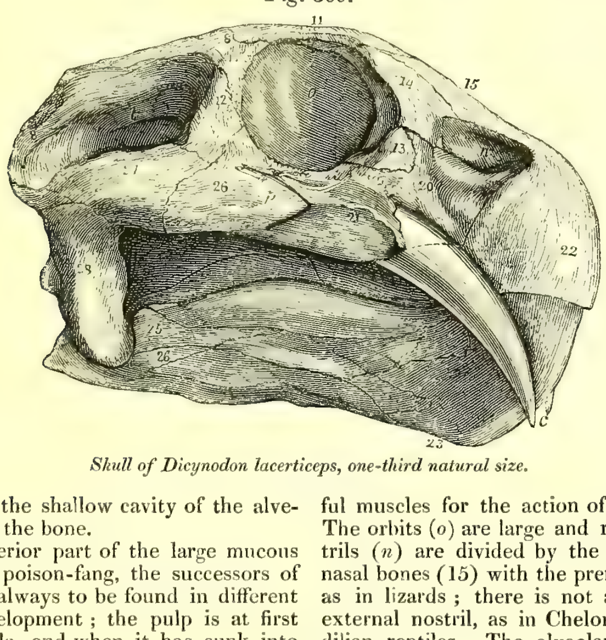
The teeth of Ophidians are developed and completed in that part which forms the original seat of the tooth-germs in all animals; viz. the mucous membrane or gum covering, the alveolar border of the dentigerous bones. This germ presents the same lax tissue, and is as abundantly developed, as in the Pike, Lophius, and many other fishes; in which it likewise serves as the nidus and locality for the complete development of the teeth. The primitive dental papillæ in the common harmless snake very soon sinks into the substance of the gum, and becomes inclosed by a capsule. As soon as the deposition of the calcareous salts commences in the apex of the papilla the capsule covering that part becomes ossified and adherent to the dentine, and the tooth begins to pierce and emerge from the gum before its mould, the pulp, is half completed. Fresh layers of cells are successively added to the base of the pulp, and converted, by their confluence and calcification, into the tubular dentine, until the full size of the tooth is attained, when its situation in the gum is gradually changed, and its base becomes anchylosed to the shallow cavity of the alveolar surface of the bone.

In the posterior part of the large mucous sheath of the poison-fang, the successors of this tooth are always to be found in different stages of development; the pulp is at first a simple papilla, and when it has sunk into the gum the succeeding portion presents a depression along its inferior surface, as it lies horizontally, with the apex directed backwards; the capsule adheres to this inflected surface of the pulp; and the base of the groove of the loose, growing, poison-fang is brought into the same relation with the duct of the poison gland as the displaced fang, which has been severed from the duct.

Saurians. — The existing species of lizards differ from those of the crocodile in the anchylosed condition of the teeth, which present few modifications of importance; those that yield most fruit to physiology, and which have most expanded our ideas of the extent of the resources of Nature and the exceptional deviations from what was deemed the rule of structure in the Saurian dentition, have been discovered by the study of the fossil teeth of extinct forms of the order. Amongst these the most extraordinary in respect of their dental system have been recently discovered in a formation in South Africa, which seems nearly as ancient as our own coal-seams. I have called them "Dicynodonts,"* from their dentition being reduced to one long and large canine tooth on each side of the upper jaw. As these teeth give, at first sight, a character to the jaws like that which the long poison-fangs give, when erected, to the jaws of the rattlesnake, I shall briefly notice their characters before entering upon the description of the more normal Saurian dentition.

Fig. 569. gives a reduced side view of the skull of the species of *Dicynodon* called *D. lacerticeps*. The cranial cavity (8, 8) is extremely contracted, as in all the cold-blooded quadrupeds: it is bounded on each side by wide and deep temporal fossæ (*t*) indicating powerful muscles for the action of the lower jaw. The orbits (*o*) are large and round; the nostrils (*n*) are divided by the junction of the nasal bones (15) with the premaxillaries (22), as in lizards; there is not a single median external nostril, as in Chelonian and Crocodilian reptiles. The alveolar border of the lower jaw and of the premaxillary part of the

Fig. 569.



Skull of Dicynodon lacerticeps, one-third natural size.

* From δὶς, two, and κυνόδους, the name given by Hippocrates to the *canine teeth*, and signifying the same idea as their common English denomination.

upper jaw is trenchant, and seems to have been sheathed with horn.

The maxillary bone (21) is excavated by a wide and deep alveolus, with a circular area of half an inch, and lodges a long and strong, slightly curved, and sharp-pointed, canine tooth or tusk, which projects about two-thirds of its length from the open extremity of the socket. The direction of the tusks is forwards, downwards, and very slightly inwards; the two converging, as they descend along the outer side of the compressed symphysis of the lower jaw (*c*). The tusk is principally composed of a body of compact unvascular dentine. The base is excavated by a wide conical pulp-cavity (*p*) with the apex extending to about one-half of the implanted part of the tusk, and a linear tract is continued along the centre of the solid part of the tusk. From this central line the dentinal tubes radiate, with a gentle curve at the beginning, convex towards the point of the tusk, and then proceeding straight to the periphery of the tooth, but inclining towards the apex. They present parallel secondary curves, divide dichotomously twice or thrice near their beginning, and send off numerous small lateral branches, chiefly from the side next the apex. At their primary curve the dentinal tubes are $\frac{1}{12000}$th of an inch in diameter, and their intervals are $\frac{1}{6000}$th of an inch across. The dentinal cells are most conspicuous near the periphery of the tooth, and vary in diameter from $\frac{1}{800}$th to $\frac{1}{1000}$th of an inch.

The enamel, at least at the middle of the tusk, is thinner than in the teeth of the crocodile. It presents only a finely lamellated texture, the layers being parallel with the surface of the dentine on which it rests. There is only a fine linear trace of cement on the exterior of the sections of the implanted base of the tusks; and here it is too thin to allow of the development of the radiated cells in its substance. There is no trace of teeth or their sockets in the lower jaw (25, 23); so much of the alveolar border as is exposed presents a smooth and even edge, which seems to have played like a scissor-blade upon the inner side of the corresponding edentulous border of the upper jaw; and it is most probable, from the analogies of similarly-shaped jaws of existing Reptilia, that the fore part of both the upper and under jaws were sheathed with horn.

Until the discovery of the *Rhynchosaurus**, this edentulous and horn-sheathed condition of the jaws was supposed to be peculiar to the Chelonian order among reptiles; and it is not one of the least interesting features of the Dicynodonts of the African sandstones, that they should repeat a Chelonian character, hitherto peculiar, amongst Lacertians, to the above-cited remarkable extinct edentulous genus of the new red sandstone of Shropshire: but our interest rises almost to astonishment, when, in a Saurian skull, we find, superadded to the horn-clad mandibles of the Tortoise, a pair of tusks, borrowed as it were from the mammalian class, or rather foreshadowing a structure which, in the actual creation, is peculiar to certain members of the highest organised warm-blooded animals.

* Transactions of the Cambridge Philosophical Society, vol. vii. part iii.

In the other Reptilia, recent or extinct, which most nearly approach the Mammalia in the structure of their teeth, the difference characteristic of the inferior and cold-blooded class is manifested in the shape, and in the system of shedding and succession, of the teeth: the base of the implanted teeth seldom becomes consolidated, never contracted to a point, as in the fangs of the simple teeth of Mammalia, and at all periods of growth one or more germs of teeth are formed within or near the base of the tooth in use, prepared to succeed it, and progressing towards its displacement. The dental armature of the jaws is kept in serviceable order by uninterrupted change and succession; but the matrix of the individual tooth is soon exhausted, and the life of the tooth itself may be said to be comparatively short.

The Dicynodonts not only manifest the higher type of free implantation of the base of the tooth in a deep and complete socket, common to Crocodilians, Megalosaurs, and Thecodonts, but make an additional and much more important step towards the mammalian type of dentition, by maintaining the serviceable state of the tusk by virtue of constant renovation of the substance of one and the same matrix, accordingly to the principle manifested in the long-lived and ever-growing tusks of the Walrus, and the scalpriform incisors of the Rodentia.

The genera of the typical family of the squamate Lacertians are arranged in two sub-families, the chief characteristics of which are derived from the dental system.

In the first group, the teeth are solid, or without any permanent internal cavity, and are very firmly anchylosed by their base to the alveolar groove upon the inner side of the jaw; so that the extremity of the tooth is slightly directed outwards. The species which present this character are called Pleodonts.

In the second group, the teeth are excavated, or retain the pulp-cavity, and are less firmly fixed to the jaws, being applied vertically, like piles or buttresses, against the outer alveolar parapet, but not adhering by their base. This group is called Cœlodonts.

The Monitor Lizard of S. America is an example of the Pleodont group, in which the premaxillary teeth are ten in number. The maxillary teeth vary from ten to fifteen on each side, and increase in size as they are placed farther back: the hindmost teeth are tricuspid in young individuals, and present the form of simple tubercles in the old Monitors. The mandibular teeth, fifteen to eighteen in number in each ramus, correspond in size and form with those above. In the Cœlodont group, the "Swift lizards" (*Tachydromus*) have the pterygoid bones armed with minute teeth. The teeth on both upper and lower jaws are of larger size, and the hinder ones are tricuspid. The true lizards (*Lacerta*) have two kinds of teeth *quoad* form; the anterior small, conical, and recurved; the posterior larger, and bi- or tri-cuspid. Some species have also pterygoid teeth; as the common *Lacerta agilis*.

In the Gigantic fossil Monitor of Maestricht, the teeth combine the Pleodont with the Acrodont* characters.

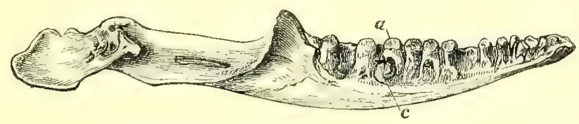
The true affinities of the Mosasaur, which was at least twenty-four feet in length, and the remains of which characterise the chalk-formations, were first determined by Cuvier, who places it in the Lacertian group of Saurians, between the Iguanæ and Monitors. Its dentition exhibits in an eminent degree the Acrodont character; the teeth being supported on expanded conical bases anchylosed to the summit of the alveolar ridge of the jaw: no existing Saurian exactly parallels this mode of attachment of the teeth, either in regard to the breadth of the alveolar border, or in the relative size of the osseous cones to the teeth which they support. A shallow socket is left where the tooth and its supporting base are shed. The form of the teeth is likewise different from that hitherto observed in any existing Saurian: the crown is pyramidal, with the outer side nearly plane, or slightly convex, and separated by two sharp ridges from the remaining surface, which forms a half-cone. All the teeth are slightly recurved, and their peripheral surface is smooth. The teeth are implanted upon the premaxillary, maxillary, and premandibulary bones; a series of similarly shaped but much smaller teeth are placed upon the pterygoid bones.

The gradual transition from the simple structure of the compact dentine to the osteodentine of the anchylosed base of the tooth was not known to Cuvier; otherwise he could not have supposed that the crown and the base of the tooth of the Mosasaurus were formed by vital processes of so dissimilar a nature as to forbid him considering them as parts of one and the same body. Cuvier had originally described the expanded base of the tooth of the Mosasaur as the root of the tooth; but afterwards, observing that the corresponding base became anchylosed by ossification of the remains of the pulp to the jaw, he conceived it to be incorrect to regard it as a part of a body which he believed to be an inorganic product, and the result of excretion. "The tooth," he observes, in correcting his first account of the Mosasaurus, "has no true root, but it adheres strongly to that pulp which has secreted it, and it is further held in connection with it by the remains of the capsule which has furnished the enamel, and which, by becoming ossified also, and uniting itself to the maxillary bone and the ossified pulp, implants or rivets the tooth with additional force."

The necessity under which Cuvier felt himself compelled to regard the crown and the base of the tooth of the Mosasaur as two distinct parts, is at once banished by the recognition of the principle, that the processes of calcification are essentially the same at every part of a tooth, whether it be free or anchylosed; and that they are modified only, as I have shown in my Memoir on the Formation of the Teeth of the Shark*, according to the density of the part to be produced.

Scincoid Lizards.—Most of these smooth-scaled lizards have small mouths and slender sharp teeth, fitted best for insect food; they are usually confined to the upper and lower jaws; but the medicinal Scink of ancient pharmacy (*Scincus officinalis*) has four or five small obtuse teeth upon each pterygoid bone. The chief exception to the typical dentition of the present family is made by the large scincoid lizards of Australia, which, on that account, have received the generic name of *Cyclodus*.†

Fig. 570.



Lower jaw and teeth of Cyclodus nigroluteus.

The dentition of the *Cycl. nigroluteus* is exemplified in the lower jaw, *fig*. 570. In the upper jaw, the single premaxillary bone has depressions for twelve teeth, of which only the alternate ones are usually in place; they are of very small size, with the fang compressed laterally, and the crown antero-posteriorly, so as to resemble a true incisor in form, the summit sloping to an edge from behind forwards, with the middle of the cutting surface a little produced. Each superior maxillary bone has depressions for fourteen teeth; they quickly increase in size, and exchange their conical for a sub-hemispherical crown; the eighth to the thirteenth inclusive are the largest teeth; they are set obliquely, and pretty close together. In the lower jaw there are two small incisors, at the anterior part of each premandibular bone corresponding with those of the premaxillary; these are succeeded by five or six conical teeth, and the rest correspond in size and form with the tuberculate molars of the upper jaw.

* Odontography, pp. 241. 258.

* Compte Rendu de l'Académie des Sciences, Decembre, 1839.

† Round-toothed: κυκλος, round; οδους, tooth.

All the teeth are attached, after the Pleurodont type, by their base and outer margin to shallow depressions on the outer side of the external alveolar parapet.

The germs of the successional teeth, *c. fig.* 570., are developed at the inner side of the base of their predecessors, *a*, which they excavate, undermine, and displace in the usual manner.

Iguanas.—Certain genera of this family of lizards, e. g. *Istiurus*, *Lophyrus*, *Calotes*, and *Otocryptis*, have the teeth soldered, like those of *Mosasaurus*, to the summit of the alveolar ridge, and thence are called "Acrodonts:" in all these lizards the maxillary and mandibular teeth may be divided into anterior laniary, and posterior molary teeth. In most of the Iguanians the teeth are lodged in a common shallow oblique alveolar groove, and are soldered to excavations on the inner surface of the outer wall of the groove: these are called Pleurodonts. Most of them possess pterygoid as well as maxillary teeth: but the following genera, *Hyperanodon*, *Tropidolepis*, *Phrynosoma*, and *Callisaurus*, are exceptions.

In the Pleurodont Iguanians, the teeth never present the true laniary form; and if simply conical, as at the extremes of the maxillary series, the cone is more or less obtuse; but, in general, it is expanded, more or less trilobate, or dentated along the margin of the crown.

The *Amblyrhynchus*, a genus which is somewhat remarkable for the marine habits of at least one of the species (*Amblyrhynchus ater*), whose diet is sea-weed*, has the tricuspid structure well developed in the posterior teeth.

The typical genus of the present family of Saurians (*Iguana tuberculata*), is characterised by the crenate or dentated margin of the crown of the maxillary and premandibular teeth, a few of the anterior small ones excepted. The pterygoid teeth are arranged in two or three irregular rows, resembling somewhat the "dents en cardes" of fishes. In the full-grown *Iguana tuberculata* there are from forty-seven to forty-nine teeth in both upper and lower jaws. The number is less in young subjects. The double row of pterygoid teeth are in close order on each side.

In the horned Iguana (*Metopoceros cornutus*), there are about fifty-six teeth in the upper and lower jaws, of which the four first are conical and slightly recurved. The twelve succeeding teeth are somewhat larger in size, with more compressed and expanded crowns; the rest are triangular, compressed, with dentated margins. The inner surface of the crown of the tooth is simply convex and smooth; the outer surface traversed by a median, longitudinal, broad, obtuse ridge. There is a single row of small teeth implanted in each pterygoid bone. No Iguanian lizard has teeth on the palatine bones.

The teeth of the *Iguanodon*, though resembling those of the Iguana, do not present an exact magnified image of them, but differ in the greater relative thickness of the crown, its more complicated external surface, and, still more essentially, in a modification of the internal structure, by which the *Iguanodon* equally deviates from every other known reptile.

As in the Iguana, the base of the tooth is elongated, contracted, and subcylindrical; the crown expanded, and smoothly convex on the inner side. When first formed, it is acuminated, compressed, its sloping sides serrated, and its external surface traversed by a median longitudinal ridge, and coated by a layer of enamel, but, beyond this point, the description of the tooth of the Iguanodon indicates characters peculiar to that genus. In most of the teeth that have hitherto been found, three longitudinal ridges (*fig.* 571.) traverse the outer surface of the crown, one on each side of the median primitive ridge; these are separated from each other, and from the serrated margins of the crown, by four wide and smooth longitudinal grooves. The relative width of these grooves varies in different teeth; sometimes a fourth small longitudinal ridge is developed on the outer side of the crown. The marginal serrations, which, at first sight, appear to be simple notches, as in the Iguana, present, under a low magnifying power, the form of transverse ridges, themselves notched, so as to resemble the mammilated margins of the unworn plates of the elephant's grinder: slight grooves lead from the interspaces of these notches upon the sides of the marginal ridges. These ridges, or dentations, do not extend beyond the expanded part of the crown: the longitudinal ridges are continued further down, especially the median ones, which do not subside till the fang of the tooth begins to assume its subcylindrical form. The tooth at first increases both in breadth and thickness; it then diminishes in breadth, but its thickness goes on increasing; in the larger and fully formed teeth, the fang de-

Fig. 571.

Unworn tooth of Iguanodon.

* This species, and probably all the known *Amblyrhynchi*, or blunt-nosed Iguanæ, inhabit the islands in the Galopagos group; their habits have been well elucidated by Mr. Darwin (Voyage of the Beagle, vol. iii. p. 466.). In specimens which he dissected, he found the stomach loaded with minced sea-weed.

creases in every diameter, and sometimes tapers almost to a point. The smooth unbroken surface of such fangs indicates that they did not adhere to the inner side of the maxillæ, as in the Iguana, but were placed in separate alveoli, as in the Crocodile and Megalosaur; such support would appear, indeed, to be indispensable to teeth so worn by mastication as those of the Iguanodon. A fracture of this tooth shows that the pulp was not entirely solidified, but that its cavity had continued open at the thickest part of the tooth.

The apex of the tooth soon begins to be worn away, and it would appear, by many specimens that have been found, that the teeth were retained until nearly the whole of the crown had yielded to the daily abrasion. In these teeth, however, the deep excavation of the remaining fang, represented in profile in the figure *fig.* 571., plainly bespeaks the progress of the successional tooth prepared to supply the place of the worn-out grinder.

At the earlier stages of abrasion, a sharp edge is maintained at the external part of the tooth by means of the enamel which covers that surface of the crown. The prominent ridges upon that surface give a sinuous contour to the middle of the cutting edge, whilst its sides are jagged by the lateral serrations. The adaptation of this admirable dental instrument to the cropping and comminution of such tough vegetable food as the *Clathrariæ* and similar plants, which are found buried with the Iguanodon, is pointed out by Dr. Buckland, with his usual felicity of illustration, in his "Bridgewater Treatise," vol. i. p. 246.

When the crown is worn away beyond the enamel, it presents a broad and nearly horizontal grinding surface, and now another dental substance is brought into use to give an inequality to that surface; this is the ossified remnant of the pulp, which, being firmer than the surrounding dentine, forms a slight transverse ridge in the middle of the grinding surface. The tooth in this stage has exchanged the functions of an incisor for that of a molar, and is prepared to give the final compression, or comminution, to the coarsely divided vegetable matters.

The marginal edge of the incisive condition of the tooth and the median ridge of the molar stage are more effectually established by the introduction of a modification into the texture of the dentine, by which it is rendered softer than in the existing Iguanæ and other reptiles, and more easily worn away: this is effected by an arrest of the calcifying process along certain cylindrical tracts of the pulp, which is thus continued, in the form of medullary canals, analogous to those in the soft dentine of the Megatherium's grinder, from the central cavity, at pretty regular intervals, parallel with the calcigerous tubes, nearly to the surface of the tooth. The medullary canals radiate from the internal and lateral sides of the pulp-cavity, and are confined to the dentine forming the corresponding walls of the tooth; their diameter is $\frac{1}{1250}$th of an inch; they are separated by pretty regular intervals, equal to from six to eight of their own diameters; they sometimes divide once in their course. Each medullary canal is surrounded by a clear substance; its cavity was occupied in the section described by a substance of a deeper yellow colour than the rest of the dentine.

The calcigerous tubes present a diameter of $\frac{1}{25,000}$th of an inch, with interspaces equal to about four of their diameters. At the first part of their course, near the pulp-cavity, they are bent in strong undulations, but afterwards proceed in slight and regular primary curves, or in nearly straight lines, to the periphery of the tooth. When viewed in a longitudinal section of the tooth, the concavity of the primary curvature is turned towards the base of the tooth; the lowest tubes are inclined towards the root, the rest have a general direction at right angles to the axis of the tooth; the few calcigerous tubes, which proceed vertically to the apex, are soon worn away, and can be seen only in a section of the apical part of the crown of an incompletely developed tooth. The secondary undulations of each tooth are regular and very minute. The branches, both primary and secondary, of the calcigerous tubes are sent off from the concave side of the main inflections; the minute secondary branches are remarkable at certain parts of the tooth for their flexuous ramifications, anastomoses, and dilatations into minute calcigerous cells, which take place along nearly parallel lines for a limited extent of the course of the main tubes. The appearance of interruption in the course of the calcigerous tubes, occasioned by this modification of their secondary branches, is represented by the irregularly dotted tracts in the figure of the dental structure of this ancient reptile given in my "Odontography." This modification must contribute, with the medullary canals, though in a minor degree, in producing that inequality of texture and of density in the dentine, which renders the broad and thick tooth of the Iguanodon more efficient as a triturating instrument.

The enamel which invests the harder dentine, forming the outer side of the tooth, presents the same peculiar dirty brown colour, when viewed by transmitted light, as in most other teeth: very minute and scarcely perceptible undulating fibres, running vertically to the surface of the tooth, is the only structure I have been able to detect in it.

The cement is simply and minutely cellular upon the crown of the tooth, but it exhibits the radiated cells at the base of the tooth.

The remains of the pulp in the contracted cavity of the completely formed tooth are converted into a dense but true osseous substance, characterised by minute elliptical radiated cells, whose long axis is parallel with the plane of the concentric lamellæ, which surround the few and contracted medullary canals in this substance.

The microscopical examination of the structure of the Iguanodon's teeth thus contributes additional evidence of the perfection of their adaptation to the offices to which their more obvious characters had indicated them to have been destined.

To preserve a trenchant edge, a partial coating of enamel is applied; and, that the thick body of the tooth might be worn away in a more regularly oblique plane, the dentine is rendered softer as it recedes from the enameled edge by the simple contrivance of arresting the calcifying process along certain tracts of the inner wall of the tooth. When attrition has at length exhausted the enamel and the tooth is limited to its functions as a grinder, a third substance has been prepared in the ossified remnant of the pulp to add to the efficiency of the dental instrument in its final capacity. And if the following reflections were natural and just after a review of the external characters of the dental organs of the Iguanodon, their truth and beauty become still more manifest as our knowledge of their subject becomes more particular and exact:

"In this curious piece of animal mechanism we find a varied adjustment of all parts and proportions of the tooth, to the exercise of peculiar functions, attended by compensations adapted to shifting conditions of the instrument, during different stages of its consumption. And we must estimate the works of nature by a different standard from that which we apply to the productions of human art, if we can view such examples of mechanical contrivance, united with so much economy of expenditure, and with such anticipated adaptations to varying conditions in their application, without feeling a profound conviction that all this adjustment has resulted from design and high intelligence."*

Varanians.—In the great Crocodilian Monitor (*Varanus crocodilinus*), the large fixed compressed teeth, of which there may be about seven in each upper maxillary bone and six in each premandibular, are anchylosed by the whole of their base and by an oblique surface leading upwards on the outer side of the tooth to a slight depression on the oblique alveolar surface, as in the *Var. striatus*. The base of the tooth is finely striated, the lines being produced by inflected folds of the external cement, as in the Ichthyosaur and Labyrinthodon, but they are short and straight, as in those of the former genus. The alveolar channel or groove has scarcely any depth; but the anchylosed base of the tooth is applied to an oblique surface, terminating in a sharp edge, from which the outer side of the free crown of the tooth is directly continued. The great *Varanus*, like the variegated species manifests its affinity to the Crocodilians in the number of successive teeth which are in progress of growth to replace each other; but from the position in which the germs of the successional teeth are developed, the more advanced teeth in this species, as in the *Var. variegatus*, do not exhibit the excavations that characterise the same parts of the teeth of the Enaliosaurs and Crocodiles.

Thecodonts.—We have seen that among the inferior or squamate Saurians there are two leading modifications in the mode of attachment of the teeth, the base of which may be either anchylosed to the summit of an alveolar ridge, or to the bottom of an alveolar groove, and supported by its lateral wall. These modifications are indicated respectively by the terms "Acrodont" and "Pleurodont." A third mode of fixation is presented by some extinct Saurians, which, in other parts of their organisation, adhere to the squamate or Lacertine division of the order, the teeth being implanted in sockets, either loosely or confluent with the bony walls of the cavity; these I have termed the "Thecodont"* Lacertians: the most ancient of all Saurians belong to this group; viz. the Thuringian Monitor, or *Protorosaurus*, and the *Palæosaurus* of the dolomitic conglomerates near Bristol. The compressed Varanian form of tooth, with trenchant and finely dentated margins, which characterised the ancient Palœosaur and Chadeiodon, is continued in the comparatively more recent and gigantic species of terrestrial lizard, of which the remains were discovered by Dr. Buckland in the oolite of Stonesfield, by whom the peculiarities of the jaws and teeth have been accurately and graphically described in the following words:—

"From these remains we learn that the animal was a reptile, closely allied to some of our modern lizards; and viewing the teeth as instruments for providing food to a carnivorous creature of enormous magnitude, they appear to have been admirably adapted to the destructive office for which they have been designed. Their form and mechanism will be best explained by reference to the figures.

"The outer margin of the jaw rises nearly an inch above its inner margin, forming a continuous lateral parapet to support the teeth on the exterior side, where the greatest support was necessary, whilst the inner margin throws up a series of triangular plates of bone forming a zigzag buttress along the interior of the alveoli. From the centre of each triangular plate, a bony partition crosses to the outer parapet, thus completing the successive alveoli. The new teeth are seen in the angle between each triangular plate, rising in reserve to supply the loss of older teeth, as often as progressive growth, or accidental fracture, may render such renewal necessary, and thus affording an exuberant provision for a rapid succession and restoration of these most essential implements. They were formed in distinct cavities, by the side of the old teeth, towards the interior surface of the jaw, and probably expelled them by the usual process of pressure and absorption, insinuating themselves into the cavities thus left vacant. This contrivance

* Buckland's Bridgewater Treatise, vol. i. p. 249.

* Odontography, part ii. p. 266.

for the renewal of teeth is strictly analogous to that which takes place in the dentition of many species of existing lizards.

"In the structure of these teeth we find a combination of mechanical contrivances analogous to those which are adopted in the construction of the knife, the sabre, and the saw. When first protruded above the gum, the apex of each tooth presented a double cutting edge of serrated enamel. In this stage, its position and line of action were nearly vertical, and its form, like that of the two-edged point of a sabre, cutting equally on each side. As the tooth advanced in growth it became curved backwards in the form of a pruning-knife, and the edge of serrated enamel was continued downwards to the base of the inner and cutting side of the tooth, whilst on the outer side a similar edge descended but a short distance from the point, and the convex portion of the tooth became blunt and thick, as the back of a knife is made thick for the purpose of producing strength. The strength of the tooth was further increased by the expansion of its side. Had the serrature continued along the whole of the blunt and convex portion of the tooth, it would in this position have possessed no useful cutting power; it ceased precisely at the point beyond which it could no longer be effective. In a tooth thus formed for cutting along its concave edge, each movement of the jaw combined the power of the knife and saw; whilst the apex, in making the first incision, acted like the two-edged point of a sabre. The backward curvature of the full-grown teeth enabled them to retain, like barbs, the prey which they had penetrated. In these adaptations we see contrivances which human ingenuity has also adopted in the preparation of various instruments of art." *

The teeth of the *Megalosaur* consist of a central body of dentine, with an investment of enamel upon the crown, and of cement over all, but thickest upon the fang. The marginal serrations are formed almost entirely by the enamel, and when slightly magnified are seen to be rounded, and separated by slight basal grooves; the smooth and polished enamel upon the sides of the crown presents a finely wrinkled appearance; the remains of the pulp are converted into a coarse bone in the completely formed tooth.

Enaliosaurs. — The teeth of the Ichthyosauri have a simple, more or less acutely conical form, with a long and, usually, expanded or ventricose base, or implanted fang. They are confined to the intermaxillary, maxillary, and premandibular bones, in which they are arranged in a pretty close and uninterrupted series, and are of nearly equal size. They consist of a body of unvascular dentine, invested at the base by a thick layer of cement, and at the crown by a layer of enamel, which is itself covered by a very thin coat of cement; the pulp-cavity is more or less occupied in fully-formed teeth by a coarse bone. The external surface of the tooth is marked by the longitudinal impressions and ridges, but the teeth vary both as to outward sculpturing and general form in the different species.*

The chief peculiarity of the dental system of the Ichthyosaur is the mode of the implantation of the teeth; instead of being anchylosed to the bottom and side of a continuous shallow groove, as in most Lacertians, or implanted in distinct sockets, as in the Thecodon, Megalosaur, or Pterodactyle, they are lodged loosely in a long and deep continuous furrow, and retained by slight ridges between the teeth, along the sides and bottom of the furrow, and by the gum and organised membranes continued into the groove and upon the base of the teeth.

The germs of the new teeth are developed at the inner side of the base of the old ones.

Crocodilia. — The best and most readily recognisable characters by which the existing Crocodilians are grouped in appropriate genera, are derived from modifications of the dental system.

In the Caimans (genus *Alligator*) the teeth vary in number from $\frac{18-18}{18-18}$ to $\frac{22-22}{22-22}$: the fourth tooth of the lower jaw, or canine, is *received into a cavity* of the palatal surface of the upper jaw, where it is concealed when the mouth is shut. In old individuals the upper jaw is perforated by these large inferior canines, and the fossæ are converted into foramina.

In the Crocodiles (genus *Crocodilus*) the first tooth in the lower jaw perforates the palatal process of the premaxillary bone when the mouth is closed; the fourth tooth in the lower jaw is *received into a notch* excavated in the side of the alveolar border of the upper jaw, and is visible externally when the mouth is closed.

In the two preceding genera the alveolar borders of the jaw have an uneven or wavy contour, and the teeth are of an unequal size.

In the Gavials (genus *Gavialis*) the teeth are nearly equal in size and similar in form in both jaws, and the first as well as the fourth tooth in the lower jaw, passes into a groove in the margin of the upper jaw when the mouth is closed.

In the alligators and crocodiles the teeth are more unequal in size, and less regular in arrangement, and more diversified in form than in the Gavials: witness the strong thick conical laniary teeth as contrasted with the blunt mammillate summits of the posterior teeth in the alligator (*fig.* 573.). The teeth of the Gavial are subequal, most of them present the form of crown, shown in *fig.* 572., long, slender, pointed, subcompressed from before backwards, with a trenchant edge on the right and left sides, between which a few faint longitudinal ridges traverse the basal part of the enamelled crown.

* Bridgewater Treatise, vol. i. p. 237.

* Odontography, pl. 73.

Fig. 572.

Teeth in different stages of formation from one alveolus of the Gavial: a is the base partly absorbed by the pressure of *b*, the successional tooth; below which is figured *c*, the germ of the next tooth to follow.

Amongst the remains of Crocodilians which are scattered through the Tilgate strata, the most common ones are detached teeth, from the difference observable in the form of which, Dr. Mantell has observed, that " they appear referable to two kinds, the one belonging to that division of crocodiles with long slender muzzles, named *Gavial*, the other to a species of *Crocodile*, properly so-called, and resembling a fossil species found at Caen."*

Dr. Mantell has obligingly communicated to me figures of well-preserved specimens of both the forms of teeth alluded to, the exactness of which I have recognised by a comparison with the specimens themselves in the British Museum.

The tooth which, from its more slender and acuminated form, approaches nearest to the character of those of the Gavial, presents a marked difference, however, from the teeth of any of the recent species of that sub-genus of Crocodilians, as well as from those of the long and slender-snouted extinct genera, called *Teleosaurus*, *Steneosaurus*, &c. I have described it†, therefore, as indicative of a distinct species, under the name of *Crocodilus cultridens*. The crown is laterally compressed, subincurved, with two opposite trenchant edges, one forming the concave, the other the convex, outline of the tooth. In the Gavial, the direction of the flattening of the crown and the situation of the trenchant edges are the reverse, the compression being from before backwards, and the edges being lateral.‡

The tooth of the *Crocodilus cultridens* thus resembles in form that of the Megalosaur, and perhaps still more those of the Argenton crocodile; but I have not observed any specimens of the Wealden teeth in which the edges of the crown were serrated, as in both the reptiles just cited. The teeth of the *Crocodilus cultridens* also present a character which does not exist in the teeth of the Megalosaur, and is not attributed by Cuvier to those of the *Crocodile d'Argenton*. The sides of the crown are traversed by a few longitudinal parallel ridges, with regular intervals of about one line, in a crown of a tooth one inch and a half in length: these ridges subside before they reach the apex of the tooth, and more rapidly at the convex than at the concave side of the crown.

Hitherto these teeth have not been found so associated with any part of the skeleton of the same species as to yield further characters of the present extinct Crocodilian; but from the above-mentioned well-marked differences between these teeth and those of all the existing species, it is most probable that the extinct crocodile formed the type of a distinct sub-genus, for which the term *Suchosaurus* has been proposed.

The second form of tooth having the generic characters of those of the crocodile, which has been discovered in the Wealden and approximate strata, is as remarkable for its thick, rounded, and obtuse crown as the teeth of the preceding species are for their slender, compressed, acute, and trenchant character. It consequently approaches more nearly to the teeth which characterise the broad and comparatively short-snouted crocodiles; but it differs from these in one of the same characters by which the tooth of the *Suchosaurus cultridens* differs from those of the Gavials, viz., in the longitudinal ridges which traverse the exterior of the crown. These are, however, more numerous, more close-set, and more neatly defined than in the *Suchosaurus cultridens*. Two of the ridges, larger and sharper than the rest, traverse opposite sides of the tooth, from the base to the apex of the crown; they are placed, as in the crocodile and Gavial, at the sides of the crown, midway between the convex and concave lines of the curvature of the tooth. These ridges are confined to the enamel; the cement-covered cylindrical base of the tooth is smooth. The size of the teeth varies from a length of crown of two inches, with a basal diameter of one inch and a half to teeth of one-third of these dimensions. I have proposed to call this extinct crocodile, with biconcave vertebræ, *Goniopholis crassidens*.

Development. — In the black alligator of Guiana the first fourteen teeth of the lower jaw are implanted in distinct sockets, the remaining posterior teeth are lodged close together in a continuous groove, in which the divisions for sockets are faintly indicated by vertical ridges, as in the jaws of the Ichthyo-

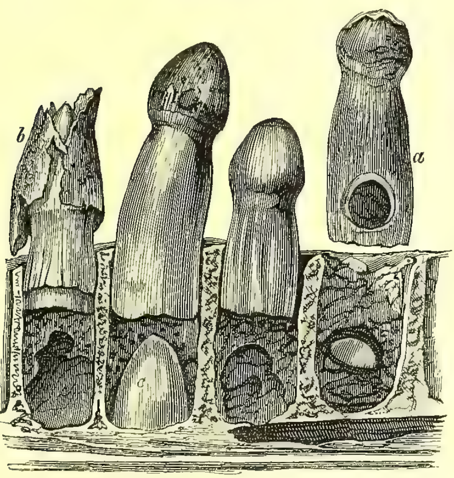
‡ The tooth attributed by M. Deslongchamps to the *Poikilopleuron*, agrees in form with those of the Gavial, and differs in the characters cited in the text from those of the *Crocodilus cultridens*.

saurs. A thin compact floor of bone separates this groove, and the sockets anterior to it, from the large cavity of the ramus of the jaw; it is pierced by bloodvessels for the supply of the pulps of the growing teeth and the vascular dentiparous membrane which lines the alveolar cavities.

The tooth-germ is developed from the membrane covering the angle between the floor and the inner wall of the socket. It becomes in this situation completely enveloped by its capsule, and an enamel-organ is formed at the inner surface of the capsule before the young tooth penetrates the interior of the pulp-cavity of its predecessor.

The matrix of the young growing tooth affects, by its pressure, the inner wall of the socket, as shown in *fig*. 573, and forms for

Fig. 573.



Section of lower jaw, with four alveoli and teeth, of the black Alligator.

itself a shallow recess: at the same time it attacks the side of the base of the contained tooth; then, gaining a more extensive attachment by its basis and increased size, it penetrates the large pulp-cavity of the previously formed tooth either by a circular or semicircular perforation. The size of the calcified part of the tooth-matrix which has produced the corresponding absorption of the previously formed tooth on the one side, and of the alveolar process on the other, is represented in the second exposed alveolus of *fig*. 573., the tooth *a* having been displaced and turned round to show the effects of the stimulus of the pressure. The size of the perforation in the tooth, and of the depression in the jaw, proves them to have been, in great part, caused by the soft matrix, which must have produced its effect by exciting vital action of the absorbents, and not by mere mechanical force. The resistance of the wall of the pulp-cavity having been thus overcome, the growing tooth and its matrix recede from the temporary alveolar depression, and sink into the substance of the pulp contained in the cavity of the fully-formed tooth. As the new tooth grows, the pulp of the old one is removed; the old tooth itself is next attacked, and the crown being undermined by the absorption of the inner surface of its base, may be broken off by a slight external force, when the point of the new tooth is exposed, as in the *fig*. 573. *b*.

The new tooth disembarrasses itself of the cylindrical base of its predecessor, with which it is sheathed, by maintaining the excitement of the absorbent process so long as the cement of the old fang retains any vital connection with the periosteum of the socket; but the frail remains of the old cylinder, thus reduced, are sometimes lifted off the socket upon the crown of the new tooth, as in *fig*. 573. *b*, when they are speedily removed by the action of the jaws. This is, however, the only part of the process which is immediately produced by mechanical force: an attentive observation of the more important previous stages of growth, teaches that the pressure of the growing tooth operates upon the one to be displaced only through the medium of the vital absorbent action which it has excited.

Most of the stages in the development and succession of the teeth of the crocodiles are described by Cuvier with his wonted clearness and accuracy; but the mechanical explanation of the expulsion of the old tooth, which Cuvier adopts from M. Tenon, is opposed by the disproportionate smallness of the hard part of the new tooth to the vacuity in the old one, and by the fact that the matter impressing — viz. the uncalcified part of the walls of the tooth-matrix — is less dense than the part impressed.

No sooner has the young tooth penetrated the interior of the old one, than another germ begins to be developed from the angle between the base of the young tooth and the inner alveolar process, or in the same relative position as that in which its immediate predecessor began to rise, and the processes of succession and displacement are carried on, uninterruptedly, throughout the long life of these cold-blooded carnivorous reptiles.

From the period of exclusion from the egg, the teeth of the crocodile succeed each other in the vertical direction; none are added from behind forwards, like the true molars in Mammalia. It follows, therefore, that the number of the teeth of the crocodile is as great when it first sees the light as when it has acquired its full size; and, owing to the rapidity of the succession, the cavity at the base of the fully-formed tooth is never consolidated.

The fossil jaws of the extinct Crocodilians demonstrate that the same law regulated the succession of the teeth, at the ancient epochs when those highly organised reptiles prevailed in greatest numbers, and under the most varied generic and specific modifications, as at the present period, when they are reduced to a single family, composed of so few and slightly varied species as to have constituted in the system of Linnæus a small fraction of his genus Lacerta.

Dental System of Mammals.

The class Mammalia, like that of *Reptilia* and *Pisces*, includes a few genera and species that are devoid of teeth: the true ant-eaters (*Myrmecophaga*), the scaly ant-eaters or Pangolins (*Manis*), and the spiny monotrematous ant-eater (*Echidna*), are examples of strictly edentulous Mammals. The *Ornithorhynchus* has horny teeth, and the whales (*Balæna* and *Balænoptera*) have transitory embryonic calcified teeth*, succeeded by whalebone substitutes† in the upper jaw. Horny processes analogous to, perhaps homologous with, the lingual and palatal teeth in fishes, are present in the *Echidna*.

The female Narwhal seems to be edentulous, but has the germs of two tusks in the substance of the upper jaw-bones; one of these becomes developed into a large and conspicuous weapon in the male Narwhal, and, accordingly, suggested to Linnæus the name, for its genus, of *Monodon*, meaning single tooth: but the tusk is never median, like the truly single tooth on the palate of the Myxine; and occasionally both tusks are developed in the Narwhal. In another Cetacean, the great Bottle-nose, or *Hyperoodon*, the teeth are reduced in the adult to two in number, whence the specific name *H. bidens*, but they are confined to the lower jaw. The sharp-nosed dolphin (*Ziphius*) has also but two teeth, one in each ramus of the lower jaw; and this is, perhaps, a sexual character. The *Delphinus griseus* has five teeth on each side of the lower jaw; but they soon become reduced to two. Amongst the marsupial animals, the genus *Tarsipes* is remarkable for the paucity as well as minuteness of its teeth.

The elephant has never more than one entire molar, or parts of two, in use on each side of the upper and lower jaws; to which are added two tusks, more or less developed, in the upper jaw.

Some Rodents, as the Australian Water-rats (*Hydromys*), have two grinders on each side of both jaws; which, added to the four cutting teeth in front, make twelve in all: the common number of teeth in this order is twenty; but the hares and rabbits have twenty-eight teeth. The sloth has eighteen teeth. The number of teeth, thirty-two, which characterises man, the apes of the old world, and the true ruminants, is the average one of the class Mammalia; but the typical number is forty-four.

The examples of excessive number of teeth are presented, in the order *Bruta*, by the Priodont Armadillo, which has ninety-eight teeth; and, in the cetaceous order, by the Cachalot, which has upwards of sixty teeth, though most of them are confined to the lower jaw; by the common porpoise, which has between eighty and ninety teeth; by the Gangetic dolphin, which has one hundred and twenty teeth; and by the true dolphins (*Delphinus*), which have from one hundred to one hundred and ninety teeth, yielding the maximum number in the class Mammalia.

Form.—Where the teeth are in excessive number, as in the species above cited, they are small, equal, or subequal, and of a simple conical form; pointed, and slightly recurved in the common dolphin; with a broad and flattened base in the gangetic dolphin (*Inia*); with the crown compressed, and broadest in the porpoise; compressed but truncate, and equal with the fang, in the Priodon. The compressed triangular teeth become coarsely notched or dentated, at the hinder part of the series, in the great extinct cetaceous *Zeuglodon*. The simple dentition of the smaller Armadillos, of the Orycterope, and of the three-toed Sloth, presents a difference in the size, but little variety in the shape of the teeth, which are subcylindrical, with broad triturating surfaces; in the two-toed Sloth, the two anterior teeth of the upper jaw are longer and larger than the rest, and adapted for piercing and tearing.

In almost all the other Mammalia, particular teeth have special forms for special uses: thus, the front teeth, from being commonly adapted to effect the first coarse division of the food, have been called cutters or *incisors*; and the back teeth, which complete its comminution, grinders or *molars*; large conical teeth, situated behind the incisors, and adapted by being nearer the insertion of the biting muscles, to act with greater force, are called holders, tearers, laniaries, or more commonly *canine* teeth, from being well developed in the dog and other Carnivora, although they are given, likewise, to many vegetable feeders for defence or combat: *e.g.* Musk-deer (*fig.* 580, VII.). Molar teeth, which are adapted for mastication, have either tuberculate, or ridged, or flat, summits; and usually are either surrounded by a fence of enamel, or are traversed by enamel plates arranged in various patterns. Certain molars in the Dugong, the Mylodon, and the Zeuglodon, are so deeply indented laterally by opposite longitudinal grooves, as to appear, when abraded, to be composed of two cylindrical teeth cemented together, and the transverse section of the crown is bilobed. The teeth of the *Glyptodon* were fluted by two analogous grooves on each side. The large molars of the Capybara and Elephant have the crown cleft into a numerous series of compressed transverse plates, cemented together side by side.

The teeth of the Mammalia have usually so much more definite and complex a form than those of fishes and reptiles, that three parts are recognised in them: viz. the "fang," the "neck," and the "crown." The fang or root (*radix*) is the inserted part; the crown (*corona*) the exposed part; and the construction which divides these is called the neck (*cervix*). The term "fang" is properly given only to the implanted part of a tooth of re-

* Odontography, pl. 87 *a*, *figs.* 1—6.

† Ib. pl. 76, *figs.* 4. 6; art. Cetacea, Vol. I. p. 572, *fig.* 259 *b*.

stricted growth, which fang gradually tapers to its extremity; those teeth which grow uninterruptedly have not their exposed part separated by a neck from their implanted part, and this generally maintains to its extremity the same shape and size as the exposed crown.

It is peculiar to the class Mammalia to have teeth implanted in sockets by two or more fangs; but this can only happen to teeth of limited growth, and generally characterises the molars and premolars; perpetually growing teeth require the base to be kept simple and widely excavated for the persistent pulp. In no mammiferous animal does anchylosis of the tooth with the jaw constitute a normal mode of attachment. Each tooth has its particular socket, to which it firmly adheres by the close co-adaptation of their opposed surfaces, and by the firm adhesion of the alveolar periosteum to the organised cement which invests the fang or fangs of the tooth; but in some of the Cetacea, at the posterior part of the dental series, the sockets are wide and shallow, and the teeth adhere more strongly to the gum than to the periosteum; in the Cachalot I have seen all the teeth brought away with the ligamentous gum, when it has been stript from the sockets of the lower jaw.

Teeth are fixed as a general rule in all Vertebrata, and the only known exceptions are those presented by certain species of fishes, *e.g.* the Sharks, Lophioids, Goniodonts. In the higher Vertebrata the movements of the teeth depend on those of the jaw-bones to which they are affixed, but appear to be independent in the ratio of the size of the tooth to the bone to which it is attached. Thus the extent of rotatory movement to which the large perforated poison fangs of the rattle-snake are subject depends upon the rotation of the small maxillary bone. So likewise the seemingly individual movements of divarication and approximation observable in the large lower incisors of the *Bathyergus* and *Macropus* *, are due entirely to the yielding nature of the symphysis uniting the two rami of the lower jaw in which those incisors are deeply and firmly implanted. It is no more a property of the teeth themselves than is that alternate removal of the lower teeth from, and bringing of them in contact with, the upper teeth of the mouth, which one sees or feels in the act of mastication.

True teeth implanted in sockets are confined, in the Mammalian class, to the maxillary, premaxillary, and mandibular, or lower maxillary bones, and form a single row in each. They may project only from the premaxillary bones, as in the Narwhal, or only from the lower maxillary bone, as in Ziphius; or be apparent only in the lower maxillary bone, as in the Cachalot; or be limited to the superior and inferior maxillaries, and not present in the premaxillaries, as in the true *Pecora*, and most *Bruta* of Linnæus; in general, teeth are situated in all the bones above mentioned. In Man, where the premaxillaries early coalesce with the maxillary bones, where the jaws are very short and the crowns of the teeth are of equal length, there is no interspace or "diastema" in the dental series of either jaw, and the teeth derive some additional fixity by their close apposition and mutual pressure. No inferior Mammal now presents this character; but its importance, as associated with the peculiar attributes of the human organisation, has been somewhat diminished by the discovery of a like contiguous arrangement of the teeth in the jaws of a few extinct quadrupeds: e. g. *Anoplotherium*, *Nesodon*, and *Dichodon*.*

The teeth of the Mammalia usually consist of hard unvascular dentine, defended at the crown by an investment of enamel, and everywhere surrounded by a coat of cement. The coronal cement is of extreme tenuity in Man, Quadrumana, and terrestrial Carnivora; it is thicker in the Herbivora, especially in the complex grinders of the Elephant; and is thickest in the teeth of the Sloths, Megatherioids, Dugong, Walrus, and Cachalot. Vertical folds of enamel and cement penetrate the crown of the tooth in the Ruminants, and in most Rodents and Pachyderms, characterising by their various forms the genera of the last two orders; but these folds never converge from equidistant points of the circumference of the crown towards its centre. The teeth of the quadrupeds of the order *Bruta* (*Edentata*, Cuv.) have no true enamel; this is absent likewise in the molars of the Dugong and the Cachalot.† The tusks of the Narwhal, Walrus, Dinotherium, Mastodon, and Elephant consist of modified dentine, which, in the last two great proboscidian animals, is properly called "ivory," ‡ and is covered by cement.

In the subjoined magnified view of a section of the molar of a Megatherium, *t* is the hard dentine, *v* the vaso-dentine, and *c* the cement (*fig.* 574).

The teeth in the Mammalia, as in the foregoing classes, are formed by superaddition of the hardening salts to pre-existing moulds of animal pulp or membrane, organised so as to insure the arrangement of the earthy particles according to that pattern which characterises each constituent texture of the tooth.

The complexity of the primordial basis, or matrix, corresponds, therefore, with that of the fully-formed tooth, and is least remarkable in those conical teeth which consist only

* See Mason Good's Book of Nature, vol. i. p. 285. 1826.

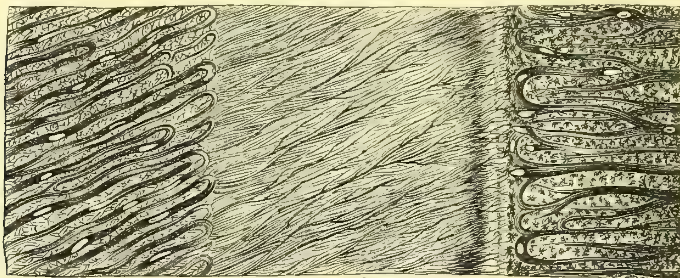
* Quarterly Journal of the Geological Society, Feb. 1848, p. 36, pl. iv.

† M. Fr. Cuvier divides the teeth of Mammalia, according to their composition, into four classes: the first consists of ivory (dentine), enamel, and cement; the second of ivory and enamel; the third of ivory and cement; the fourth of ivory only. (Dents des Mammifères, p. xxi.) I have met with no Mammalian teeth in which cement is absent, and believe that the second and fourth of the above-cited classes of teeth have no existence in nature.

‡ "Hoc solum est ebur." *Plinius, Hist. Nat.* lib. xi. c. 37.

of dentine and cement. The primary pulp, which first appears as a papilla rising from the

Fig. 574.



ree surface of the alveolar gum, is the part of the matrix which by its calcification constitutes the dentine; it sinks into a cell and becomes surrounded by a closed capsule in every mammiferous species, at an early stage of the formation of the tooth; and, as the cement is the result of the ossification of the capsule, every tooth must be covered by a layer of that substance. In those teeth which possess enamel, the mould or pulp of that constituent is developed from the capsule covering the coronal part of the dentinal pulp. In the simple teeth the secondary or enamel pulp covers the crown like a cap; in the complex teeth it sends processes into depressions of the crown, which vary in depth, breadth, direction, and number in the numerous groups of the herbivorous and omnivorous quadrupeds. The dentinal pulp, thus penetrated, offers corresponding complications of form; and as the capsule follows the enamel pulp in all its folds and processes, the external cavities or interspaces of the dentine become occupied by enamel and cement; the cement, like the capsule which formed it, being the outermost substance, and the enamel being interposed between it and the dentine. The dental matrix presents the most extensive interdigitation of the dentinal and enamel pulps in the Capybara and Elephant. The processes of formation and calcification of the several constituents of Mammalian teeth will be found described in the Introduction to my "Odontography"* and in the article Tooth.

The matrix of the Mammalian tooth sinks into a furrow and soon becomes inclosed in a cell in the substance of the jaw-bone, from which the crown of the growing tooth extricates itself by exciting the absorbent process, whilst the cell is deepened by the same process and by the growth of the jaw into an alveolus for the root of tne tooth. Where the formative parts of the tootn are reproduced indefinitely to repair by their progressive calcification the waste to which the working surface of the crown of the tooth has been subject, the alveolus is of unusual depth, and of the same form and diameter throughout, except in the immature animal, when it widens to its bottom or base. In teeth of limited growth, the dentinal pulp is reproduced in progressively decreasing quantity after the completion of the exterior wall of the crown, and forms by its calcification one or more roots or fangs, which taper more or less rapidly to their free extremity. The alveolus is closely moulded upon the implanted part of the tooth; and it is worthy of special remark that the complicated form of socket which results from the development of two or more fangs is peculiar to animals of the class Mammalia.*

In the formation of a single fang the activity of the reproductive process becomes enfeebled at the circumference, and is progressively contracted within narrower limits in relation to a single centre, until it ceases at the completion of the apex of the fang; which, though for a long time perforated for the admission of the vessels and nerves to the interior of the tooth, is, in many cases, finally closed by the ossification of the remaining part of the capsule.

When a tooth is destined to be implanted by two or more fangs, the reproduction of the pulp is restricted to two or more parts of the base of the coronal portion of the pulp, around the centre of which parts the sphere of its reproductive activity is progressively contracted. The intervening parts of the base of the coronal pulp adhere to the capsule, which is simultaneously calcified with them, covering those parts of the base of the crown of the tooth with a layer of cement. The ossification of the surrounding jaw being governed by the changes in the soft, but highly organised, dental matrix, fills up the

* P. xli.

* On the strength of this generalisation, I have established the Mammalian nature of the huge extinct animal called *Basilosaurus* by Dr. Harlan, and have advocated the claims of the diminutive *Amphitherium* and *Phascolotherium* of the oolitic slate of Stonesfield to be admitted into the same high class, against the objections raised by M. de Blainville. See "Comptes Rendus de l'Acad. des Sciences," Oct. 22, 1838. The bifid base of the teeth of certain sharks not being implanted in a socket, forms no true exception to the rule enunciated in the text. See Geological Transactions, 2d series, vol. vi. p. 66.

spaces unoccupied by the contracted and divided pulp, and affords, by its periosteum, a surface for the adhesion of the cement or ossified capsule covering the completed part of the tooth.

The matrix of certain teeth does not give rise during any period of their formation to the germ of a second tooth, destined to succeed the first; this, therefore, when completed and worn down, is not replaced: all the true Cetacea are limited to this simple provision of teeth. In the Armadillos, Megatherioids, and Sloths, the want of germinative power, as it may be called, in the matrix is compensated by the persistence of the matrix, and by the uninterrupted growth of the teeth.

In most other Mammalia, the matrix of the first developed tooth gives origin to the germ of a second tooth, which sometimes displaces, sometimes takes its place by the side of, its predecessor and parent. All those teeth which are displaced by their progeny are called temporary, deciduous, or milk teeth; the mode and direction in which they are displaced and succeeded, — viz., from above downwards in the upper, from below upwards in the lower, jaw; in both jaws vertically—are the same as in the Crocodile; but the process is never repeated more than once in any mammiferous animal. A considerable proportion of the dental series is thus changed; the second, or permanent teeth, having a size and form as suitable to the jaws of the adult, as the displaced temporary teeth were adapted to those of the young, animal. The permanent teeth, which assume places not previously occupied by deciduous ones, are always the most posterior in their position, and generally the most complex in their form. The successors of the deciduous incisors and canines differ from them chiefly in size; the successors of the deciduous molars may differ likewise in shape, in which case they have always less complex crowns than their predecessors.*

The "bicuspids," in Human Anatomy, and the corresponding teeth, called "premolars," in the lower Mammals, illustrate this law.

The first true molar owes the germ of its matrix to a vegetation or bud, separated by the fissiparous process from the matrix of the last deciduous tooth; but the backward elongation of the jaw affords space for its development by the side of its progenitor, during which process it may in like manner give origin to a second, and this to a third, molar, succeeding each other from before backwards or horizontally.

In this successive germ-production, we find repeated the multiparous property of the dental matrix of the crocodile; but the concomitant growth of the jaw allows the second, third, and sometimes fourth generation of true molars to co-exist, and come into place side by side. In the Unguiculate, and most of the Ungulate, species of the placental division of the Mammalian class, the fissiparous reproduction of horizontally succeeding teeth stops at the third generation; in other words, they have not more than three true molars on each side of the upper and lower jaws. In the Marsupial series, the same process extends to a fourth generation of true or horizontally succeeding molars*; and in most of the species, the four true molars are in use and place at the same time; but in certain Kangaroos, the anterior ones are shed before the posterior ones are developed. This successive decadence is still more characteristic of the grinding teeth of the Elephant, which are finally reduced to a single molar tooth on each side of both jaws.

Thus the class Mammalia, in regard to the times of formation and the succession of the teeth, may be divided into two groups: — the "*Monophyodonts*,"† or those that generate a single set of teeth; and the "*Diphyodonts*,"‡ or those that generate two sets of teeth.

The Monophyodonts include the orders *Monotremata*, *Bruta* (*Edentata*, Cuv.), and *Cetacea* (*Cetacea vera*, Cuv.): all the rest of the order are Diphyodonts. In these, the first set of teeth are called the milk or deciduous teeth: the second set, the adult or permanent teeth; although the teeth of this set are for the most part, like those of the first set, of limited growth, contracting to a root or roots, and being shed in greater or less proportion during the life-time of the species; which life-time, in wild Carnivora and Herbivora, is dependent on, and would seem, indeed, to be determined by, the duration of the adult teeth.

The particulars of the Monophyodont dentition will be found under the Articles MONOTREMATA, Vol. III. p. 387.; CETACEA, Vol. I. pp. 563. 571. 573.; (see my Odontography, p. 345. pls. 87—91.); and EDENTATA, Vol. II. p. 53.; (see also Odontography, p. 317. pls. 76—86.) Examples of some of the striking modifications of dental structure presented by recent or extinct animals of the order *Bruta*, are given in *figs.* 548. and 574. of the present article. It will be observed that I have qualified the generalisation as regards the Monophyodont character of the *Cetacea*, by citing only that part of Cuvier's order which he termed "true or carnivorous Cetacea." The animals of the order *Sirenia*

* "C'est une règle générale, que les molaires de remplacement ont une couronne moins compliquée que celles auxquelles elles succèdent; mais cette couronne compliquée se trouve reportée sur les molaires permanentes qui viennent plus en arrière." This generalisation was established by Cuvier, in his Leçons d'Anat. Comp., ed. 1805. vol. iii. p. 135.

* This characteristic extension of the reproductive power of the matrices of the true molars in the Marsupials, is an approximation to the peculiar activity and persistence of the same power in the vertically succeeding teeth of the cold-blooded Ovipara, and is associated with many other instances of the same affinity in more important parts of the organization of the implacental Mammals.

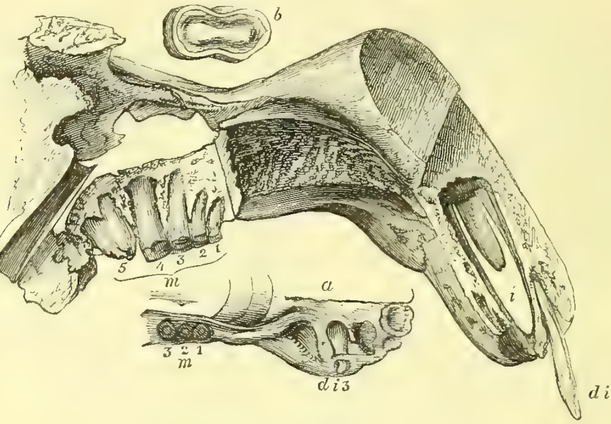
Fig. 575.



Dentition of the Dugong (Halicore indicus).

(herbivorous Cetacea of Cuvier) differ in many organic particulars from the *Cetacea* proper*, and in none, perhaps, more strikingly than in having both deciduous and permanent teeth; this succession takes place, at least, with regard to the upper incisors of the *Dugong*, *fig.* 575.

These teeth project from the gum in the male sex; but neither upper nor lower incisors are visible in the female.† The superior incisors are but two in number, in both sexes; in the male, they are moderately long, subtriedral, slightly and equally curved, of the same diameter from the base, and deeply excavated to near the apex, which is obliquely bevelled off to a sharp edge, like the scalpriform teeth of the *Rodentia.* The form and extent of the persistent pulp-cavity of this tooth are shown in the figure of its longitudinal section, in my "Odontography," pl. 93. *fig.* 4.; it becomes longer and more pointed than in the permanent incisor of the younger male (*fig.* 575, *i*). When fully developed, only the extremity of this tusk projects from the jaw, at least seven-eighths of its extent being lodged in the socket, the parietes of which are entire; and the exterior of the great premaxillary bones presents an unbroken surface. In the female Dugong, the growth of the permanent incisive tusks of the upper jaw is arrested before they cut the gum, and they remain through life concealed in the premaxillaries; the tusk is solid, is about an inch shorter and less bent than that of the male; it is also irregularly cylindrical, longitudinally indented, and it gradually diminishes to an obtuse rugged point; the base is suddenly expanded, bent obliquely outwards, and presents a shallow excavation. These were conjectured by Home to be the "milk-tusks;" they are, however, characteristic of sex, not of age; and the existence of deciduous tusks at any period in the Dugong has been called in question.* I have, however, discovered in specimens of the Malayan Dugong which I have dissected at the Zoological Society, the true deciduous incisors of the upper jaw (*fig.* 575, *d i*) coexisting with the permanent ones (*i*). They are much smaller than the permanent tusks of the female, and are loosely inserted by one extremity in conical sockets immediately anterior to those of the permanent tusks, adhering by their opposite ends to the thick tegumentary gum, which presented no outward indication of their presence.

When this gum was stripped off the bone, the deciduous tusks came away with it; and this may account for their usual absence in dried crania of immature Dugongs, in which, nevertheless, their alveoli are generally sufficiently conspicuous. True permanent incisors are not developed in the lower jaw of the Dugong; those which are occasionally found there are abortive remnants of the first or deciduous series, which are not destined at any time to rise above the gum (*fig.* 575, *d i* 3.).

The molar teeth of the Dugong resemble those of the order *Bruta* in the total absence of enamel, and of any constriction defining the crown from the fangs. In the Malayan species, only five molars (*fig.* 575, 1, 2, 3, 4, 5.) are developed on each side of both jaws: in the Australian Dugong six are developed; *i. e.* the *Halicore indicus* is characterised by the molar formula $m. \frac{5-5}{5-5}=20$, whilst the *Halicore australis* has $m. \frac{6-6}{6-6}=24$.† But in both species, the number is progressively reduced, by the shedding of the anterior and smaller molars, to $m. \frac{2-2}{2-2}=8$. The structure of these molar teeth is illustrated in

* Proceedings of the Zoological Society of London, 1838, p. 40.

fig. 546. B, their form in *fig.* 546. A; the last molar, when it comes into use, presents a bilobed form of grinding surface, as is shown at *b*, *fig.* 575.

Owing to there being but one set of molars in the Dugong, those teeth cannot be divided into true and false molars, any more than in the Sloths or Armadillos. In the true Diphyodonts, in which each kind of teeth have deciduous predecessors, those grinders which succeed the deciduous ones vertically, and displace them, are called "premolars," or "false molars," and those that come into place behind these, without pushing out vertically any predecessors, are the "molars proper," or "true molars." In this article, as in my "Odontography," the two sorts of grinders are called respectively "premolars" and "molars." In the Marsupial order the normal number of molars is four in each dental series, *i.e.* $m. \frac{4-4}{4-4}$; in the placental Diphyodonts their normal number is three, *i. e.* $m. \frac{3-3}{3-3}$; the normal number of premolars in the Marsupialia is $\frac{3-3}{3-3}$, but in the Placentalia, it is $\frac{4-4}{4-4}$: in both the numerical character of the canines is one, *i. e.* $\frac{1-1}{1-1}$; that of the incisors three, *i. e.* $\frac{3-3}{3-3}$. As regards the latter teeth, however, the number of exceptions in the *Marsupialia* is considerable, and the incisors are sometimes in excess; whilst in the placental Diphyodonts, the incisors never exceed the typical number, but frequently depart from it by suppression or arrest of development.

In fishes and reptiles, certain teeth might be called "incisive," "laniary," or "molar" teeth, in reference to the special adaptation of their form for cutting, tearing, or bruising; but such terms, in the cold-blooded classes, imply nothing more than those modifications of form; they are not significative of constant and well-defined groups of teeth, and could not become the names of definite parts or organs determinable and traceable from one species to another. In the Mammalian orders, with two sets of teeth, these organs acquire fixed individual characters, receive special denominations, and can be determined from species to species. This individualisation of the teeth is eminently significative of the high grade of organisation of the animals manifesting it; especially when we consider the great proportion of mineral substance which enters into the composition of those parts; in the number and nature of which the principle of vegetative repetition, and the power of the general polarising forces, have been most controlled in the Mammalia.

Originally, indeed, the name "incisors," "laniaries" or "canines," and "molars" were given to the teeth, in Man and certain mammals, as in reptiles, in reference merely to the shape and offices so indicated; but they are now used as arbitrary signs, in a more fixed and determinate sense. In some Carnivora, *e.g.*, the front teeth have broad tuberculate summits, adapted for nipping and bruising, while the principal back teeth are shaped for cutting, and work upon each other like the blades of scissors. The front teeth in the elephant project from the upper jaw, in the form, size, and direction of long pointed horns. In short, shape and size are the least constant of dental characters in the Mammalia; and the homologous teeth are determined, like other parts, by their relative position, by their connections, and by their development.

Those teeth which are implanted in the premaxillary bones, and in the corresponding part of the lower jaw, are called "incisors," whatever be their shape or size. The tooth in the maxillary bone, which is situated at, or near to, the suture with the premaxillary, is the "canine," as is also that tooth in the lower jaw which, in opposing it, passes in front of its crown when the mouth is closed. The other teeth of the first set are the "deciduous molars;" the teeth which displace and succeed them vertically are the "premolars;" the more posterior teeth, which are not displaced by vertical successors, are the "molars" properly so called.

When the premolars and the molars are below their typical number, the absent teeth are missing from the fore-part of the premolar series and from the back part of the molar series. The most constant teeth are the fourth premolar and the first true molar; and, these being known by their order and mode of development, the homologies of the remaining molars and premolars are determined by counting the molars from before backwards, *e. g.* "one," "two," "three;" and the premolars from behind forwards, *e. g.* "four," "three," "two," "one." The incisors are counted from the median line, commonly the foremost part of both upper and lower jaws, outwards and backwards. The first incisor of the right side is the homotype, transversely, of the contiguous incisor of the left side in the same jaw, and, vertically, of its opposing tooth in the opposite jaw; and so with regard to the canines, premolars, and molars; just as the right arm is the homotype of the left arm in its own segment, and also of the right leg of a succeeding segment. It suffices, therefore, to reckon and name the teeth of one side of either jaw in a species with the typical number and kinds of teeth; *e.g.* the first, second, and third incisors,—the first, second, third, and fourth premolars,—the first, second, and third molars; and of one side of both jaws in any case.

The homologous teeth being thus determinable, they may be severally signified by a symbol as well as by a name. The incisors, *e.g.*, by their initial letter *i.*, and individually by an added number, *i.* 1, *i.* 2, and *i.* 3; the canines by the letter *c.*; the premolars by the letter *p.*; and the molars by the letter *m.*; these also being differentiated by added numerals. Thus, the number of these teeth, on each side of both jaws, in any given species, Man *e.g.*, may be expressed by the following brief formula: — $i.\ \frac{2-2}{2-2},\ c.\ \frac{1-1}{1-1},\ p.\ \frac{2-2}{2-2},\ m.\ \frac{3-3}{3-3}=32$; and the homologies of the individual teeth, in relation to the typical formula, may be signified by *i.* 1., *i.* 2.; *c.*; *p.* 3., *p.* 4.; *m.* 1., *m.* 2., *m.* 3.: the suppressed teeth being *i.* 3.*, *p.* 1., and *p.* 2.

Examples of the typical dentition are exceptions in the actual creation; but it was the rule in the forms of Mammalia first introduced into this planet; and that, too, whether the teeth were modified for animal or vegetable food. *Fig.* 576., *e. g.*, shows the dental series

beast, the *Hyænodon;* the fossil remains of a species of which have been discovered in the oldest tertiary deposits of Hampshire. The symbols denote the homologies of the teeth.

* I have been guided by the analogy of the hare (Odontography, p. 410, pl. 104, *fig.* 5.) in this determination; but a contradictor might indulge his instinct without liability to disproof from actual knowledge.

The true molars in the one are tuberculate, indicating its tendency to vegetable diet; in the other, they are carnassial, and betoken a peculiarly destructive and bloodthirsty species.

In the Quarterly Geological Journal, No. 13, 1848, p. 36. pl. iv., I have described and figured the entire dental series of one side of the lower jaw of an extinct hoofed quadruped, the *Dichodon cuspidatus,* from eocene or oldest tertiary strata, also manifesting the normal number and kinds of teeth, but with such equality of height of crown, that no interspace is needed to lodge any of the teeth when the jaws are closed, and the series is as entire and uninterrupted as in the human subject. A great proportion of the upper jaw and teeth has been discovered, and the marks of abrasion on the lower teeth prove the series above to have been as entire and continuous as that below. The *Anoplotherium* (" Odontography," pl. 135. *fig.* 1.), from the gypsum quarries of Montmartre, geologically as ancient as the eocene clays of this island, long ago presented to Cuvier the same peculiar continuous dental series as is shown in the *Dichodon.* In his original Memoir, Cuvier described the canines as a fourth pair of incisors, on account of their small size and their trenchant shape; but he afterwards recognised their true homology with the larger and more laniariform canines of the *Palæotherium* ("Odontography," pl. 135., *fig.* 4.). The *Chæropotamus**, the *Anthracotherium*†, the *Hyopotamus*‡, the *Hyracotherium*§, the *Oplotherium*, the *Merycopotamus*, the *Hippohyus*, and other ancient (eocene and miocene) tertiary mammalian genera presented the forty-four teeth, in number and kind according to that which is here propounded as the typical or normal dentition of the placental Mammalia. Amongst the existing genera, the hog (*Sus*) is one of the few that retain this type. *Fig.* 578. shows the entire permanent series, exposed, in both jaws, and indicated individually by their symbols. *Fig.* 579. illustrates the phenomena of development which distinguish the premolars from the molars. The first premolar, *p.* 1, and the first molar, *m.* 1, are in place and use, together with the three deciduous molars, *d.* 2, *d.* 3, and *d.* 4; the second molar, *m.* 2, has just begun to cut the gum; *p.* 2, *p.* 3, and *p.* 4, together with *m.* 3, are more or less incomplete and concealed in their closed alveoli.

The premolars must displace deciduous molars in order to rise into place; the molars have no such relations; it will be observed, that the last deciduous molar, *d.* 4, has the same relative superiority of size to *d.* 3 and *d.* 2 which *m.* 3 bears to *m.* 2 and *m.* 1; and the crowns of *p.* 3 and *p.* 4 are of a more simple form than those of the milk-teeth which they are destined to succeed.

Teeth of each of the kinds above determined, and arbitrarily named "incisors," "canines," "premolars," "molars," have received other special names in regard to certain peculiarities of form or other property; and the ablest comparative anatomists have been led astray in determining their homologies when they have suffered themselves to be guided exclusively by morphological characters. The premolars in the human subject have been called "bicuspids." The last upper premolar and the first lower true molar in the Carnivora are termed, from their peculiar form, "sectorials," or "carnassial teeth," "molaires carnassières" of Cuvier. Teeth

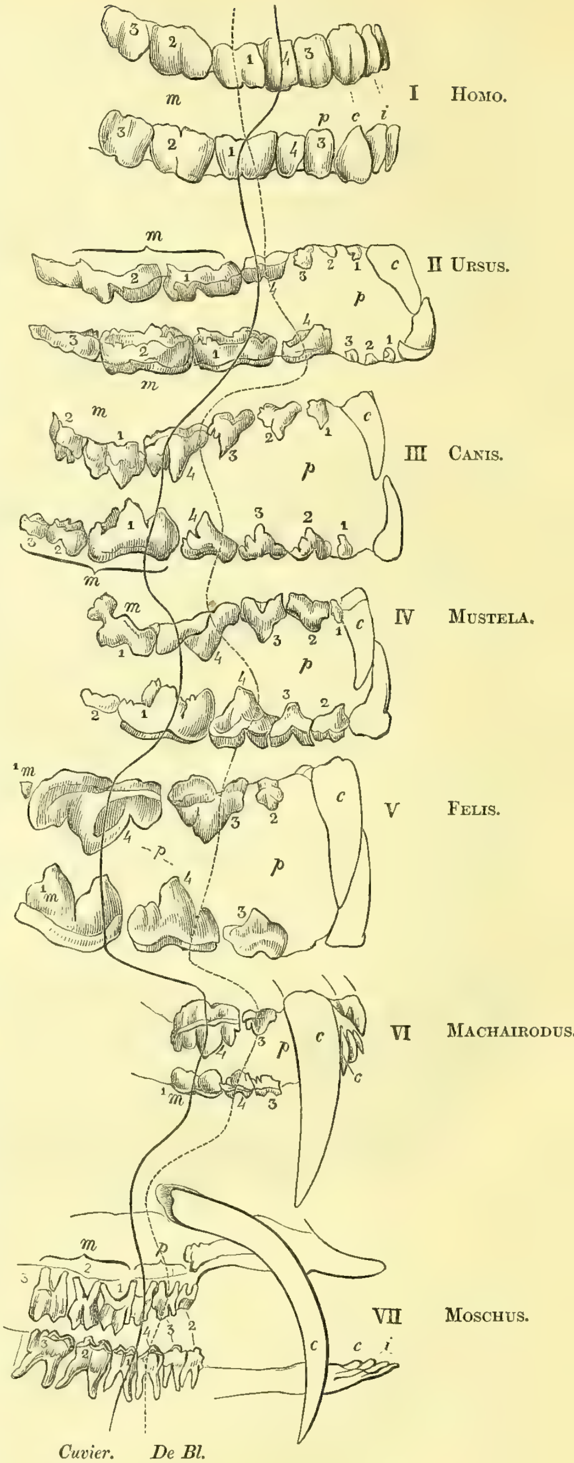
§ Geological Transactions, 2nd series, vol. vi. p. 203.

of an elongated conical form, projecting considerably beyond the rest, and of uninterrupted growth, are called "tusks;" such are the incisors of the Elephant and Dugong, the canines of the Boar and Walrus: the long and large incisors of the Rodents have been termed, from the shape and structure of their cutting edge, scalpriform or chisel-teeth, "*dentes scalprarii.*" The inferior incisors of the flying Lemurs (*Galeopithecus*) have the crown deeply notched like a comb, and are termed "*dentes pectinati.*" The canines of the Baboons are deeply grooved in front, like the poison-fangs, "*dentes canaliculati,*" of some serpents. The compressed conical crowns of the molar teeth of the small clawed seals (*Stenorhynchus*) are divided either like a trident, into three sharp points, or like a saw, into four or five points; the molars of the great extinct *Zeuglodon* had a similar form; such teeth have been called *dentes serrati.* But the philosophical course of the knowledge of nature tends to explode needless terms of art, invented for unimportant varieties, and to establish and fix the meaning of those terms that are the signs of determinate species of things.

The Cuviers divided the molar series of teeth, according to their form, into three kinds: "false molars," "carnassials," and "tubercular molars;" and, in giving the generic characters of Mammalia, based the dental formulæ on this system: thus the genus *Felis* is characterised as having "fausses molaires $\frac{2-2}{2-2}$, carnassières $\frac{1-1}{1-1}$, tuberculeuses $\frac{1-1}{0-0}$; $=\frac{8}{6}$."*

The uninterrupted line marked "Cuvier" in V. Felis of *fig.* 580., intersects the teeth in each jaw called carnassières; those anterior to them being the teeth called "fausses molaires;" the single tooth behind in the upper jaw is the "tuberculeuse." Most Zoologists, both at home and abroad, have adopted the Cuvierian system of formalising the molar teeth. It seems a very natural one in the case of the Cat

Fig. 580.



Homologies of the teeth in Diphyodont Mammals.

* "Les Dents des Mammifères considérées comme Caractères zoologiques," 8vo. p. 77. In the original the numbers are given f. m. $\frac{4}{4}$; c. $\frac{2}{2}$; t. $\frac{2}{0}$, the teeth of each side being clubbed together; they are distinguished into right and left in the text, to facilitate the comparison with the formulæ used in this Article.

genus; the tooth *p.* 4 above plays upon that, *m.* 1, below, which has a similar remarkable carnassial modification of form; they fit, indeed, almost as Cuvier describes, like the blades of a pair of scissors; the two teeth in advance of the carnassial in the upper jaw (*p.* 3, *p.* 2) in like manner are opposed to the same number of "fausses molaires" (*p.* 4, *p.* 3) in the under jaw, and the canine *c.* above plays upon the canine below; all seems straightforward and symmetrical, save that the little tubercular, *m.* 1, above has no opponent in the lower jaw. And, perhaps, the close observer might notice that, whilst the upper canine, *c.*, glides behind its homotype below, the first upper false molar (*p.* 2) passes anterior to the crown of the first false molar (*p.* 3) below; and that the second false molar and carnassial of the upper jaw are also a little in advance of those teeth in the under jaw when the mouth is shut.

In passing to the dentition of the Dog (*fig.* 580, III. Canis), formulised by Cuvier as: "fausses molaires $\frac{3-3}{4-4}$, carnassières $\frac{1-1}{1-1}$, tuberculeuses $\frac{2-2}{2-2}$; $= \frac{12}{14}$," it will be observed that here the first upper false molar (*p.* 1) differs from that in *Felis*, inasmuch as, when the mouth is shut, it preserves the same relative position to its opponent below (*p.* 1) which the upper canine does to the lower canine, and that the same may be said of the second and the third false molars; but that with regard to the carnassial above (*p.* 4) this tooth repeats the same relative position in regard to the fourth false molar below (*p.* 4), and not to that tooth, *m.* 1, which Cuvier regarded as the lower homotype of the carnassial; and, indeed, the more backward position of the lower carnassial is so slight that its significance might well be overlooked, more especially as the two succeeding tubercular teeth above were opposed to two similar tuberculars below. Cuvier therefore leaves us to conclude that the tooth which had no homotype or answerable opponent above was either the fourth "fausse molaire" below, or else the first. How unimportant size and shape are, and how significant relative position is in the determination of the homologies of teeth as of other parts, may be learnt before quitting the natural order of Carnivora; *e. g.* by the condition of the dental system in the Bear (*fig.* 580, II. Ursus). Here the lower tooth, *m.* 1, instead of presenting the carnassial character, and resembling in form the upper tooth (*p.* 4), which is the homologue of the upper carnassial in the dog, has a tubercular crown, and corresponds in size as well as shape with the upper tooth *m.* 1, to which it is almost wholly opposed, and with the same slight advance of position which we observe in the lower canine as compared with the upper one, and in the four lower premolars (*p.* 1, *p.* 2, *p.* 3, *p.* 4) as compared with their veritable homotypes above. F. Cuvier divides the molar series of the genus *Ursus* into "fausses molaires $\frac{3-3}{4-4}$, carnassières $\frac{1-1}{1-1}$, tuberculeuses $\frac{2-2}{2-2} = \frac{12}{14}$."

The tendency in every thinker to generalise and to recognise Nature's harmonies, has led him here to use the term "carnassière" in an arbitrary sense, and to apply it to a tooth above (*p.* 4), which he owns has such a shape and diminished size as would have led him to regard it as merely a false molar, but that the upper carnassial would then have entirely disappeared; and it has also led him to give the name "carnassière" to a tooth below, *m.* 1, which he, nevertheless, describes as having a tubercular and not a trenchant crown. In so natural a group as the true Carnivora it was impossible to overlook the homologues of the trenchant carnassials of the lion, even when they had become tubercular in the omnivorous bear; and Cuvier therefore, having determined and defined the teeth so called in the feline genus, felt compelled to distinguish them by the same names after they had lost their specific formal character. And if, indeed, he had succeeded in discovering the teeth which were truly answerable or homotypal in the upper and lower jaws, the term "carnassial" might have been retained as an arbitrary one for such teeth, and have been applied to their homologues in Man, the Ruminant, or the Pachyderm, where they are as certainly determinable as in those aberrant Carnivores, in which they have equally lost their sectorial shape. But the inconvenience of names indicative of such specialties of form will be very obvious when the term "tuberculeuses" comes to be applied to the three hindmost teeth in the *Hyænodon* (*fig.* 577.), which teeth answer to the broad crushing teeth, *m.* 1, *m.* 2, and *m.* 3, in the bear and some other existing Carnivora. The analogous term "molar," having a less direct or descriptive meaning, is therefore so much the better as the requisite arbitrary name of a determinate species of teeth.

Had Cuvier been guided in his determinations of the teeth by their mutual opposition in the closed mouth, and had studied them with this view in the Carnivora, with the dentition most nearly approaching to the typical formula, viz. the bear, he could then have seen that the three small and inconstant lower premolars (*p.* 1, *p.* 2, *p.* 3) were the homotypes of the three small and similarly inconstant premolars above; that the fourth false molar (*p.* 4) below, which, as he observes, "alone has the normal form," * was truly the homotype of the tooth above (*p.* 4), which he found himself compelled to reject from the class of "fausses molaires," notwithstanding it presented their normal form; that the tubercular tooth, *m.* 1, which he calls "carnassière" in the lower jaw, was the veritable homotype of his first "molaire tuberculeuse" above (*m.* 1), and that the tooth in the inferior series which had no answerable one above was his second "tuber-

* Dents des Mammifères, p. 111.

culeuse" (my *m.* 3), and not any of the four false molars. The true second tubercular above (*m.* 2) is, however, so much developed in the bear as to oppose both *m.* 2 and *m.* 3 in the lower jaw, and it might seem to include the homotypes of both those teeth coalesced. One sees with an interest such as only these homological researches could excite, that they were distinctly developed in the ancient *Amphicyon* (*fig.* 576.), which accordingly presents the typical formula. Thus, I repeat, the study of the relative position of the teeth of the bear might have led to the recognition of their real nature and homologies, and have helped to raise the mask of their extreme formal modifications, by which they are adapted to the habits of the more bloodthirsty Carnivora. But the truth is plainly and satisfactorily revealed when we come to trace the course of development and succession of these teeth. The weight which must ever attach itself to an opinion sanctioned by the authority of both the Cuviers, demands that a conclusion contrary to theirs, and which seems to be opposed by Nature herself in certain instances, should be supported by all the evidence of which such conclusion is susceptible.

I proceed, therefore, to show how, in the bear, my determinations of the teeth are established by their development, as well as by their relative position. As the question only concerns the molar series, the remarks will be confined to these. In the jaws of the young bear, figured in cut 581., the first premolar, *p.* 1, is the only one of the permanent series in place; similarity to *p.* 4 in the lower jaw (*fig.* 581, Ursus), to be veritably the last of the premolar series, and to agree not in shape only, but in every essential character, with the three preceding teeth called by Cuvier "fausses molaires." So, likewise, in the lower jaw, we see that the primitive deciduous series, *d.* 1, *d.* 2, *d.* 3, and *d.* 4, will be displaced by the corresponding premolars, *p.* 1, *p.* 2, *p.* 3, and *p.* 4; and that the tooth *m.* 1, called carnassière by Cuvier, in the lower jaw, differs essentially from that *p.* 4, so called in the upper jaw by being developed without any vertical predecessor or deciduous tooth.

The same law of development and succession prevails in the genus *Canis* (*fig.* 582.). Although the tooth *m.* 1 in the lower jaw has exchanged the tubercular for the carnassial form, it is still developed, as in the bear, behind the deciduous series, and independently of any vertical predecessor; and the tooth *p.* 4 above, although acquiring a relative superiority of size to its homologue in the bear, and more decidedly a carnassial form, is not the homotype of the permanent carnassial below, but of that premolar (*p.* 4) which is destined to displace the deciduous carnassial *d.* 4. The symbols sufficiently indicate the relations of the other teeth, and the conclusions that are to be drawn from them as to their homologies. It is interesting to observe in the deciduous, as well as in the permanent series, that the lower carnassial *d.* 4 is not the homotype of the upper one *d.* 3, but of the tooth which Cuvier calls the "tuberculeuse du lait," *d.* 4 in the upper jaw.

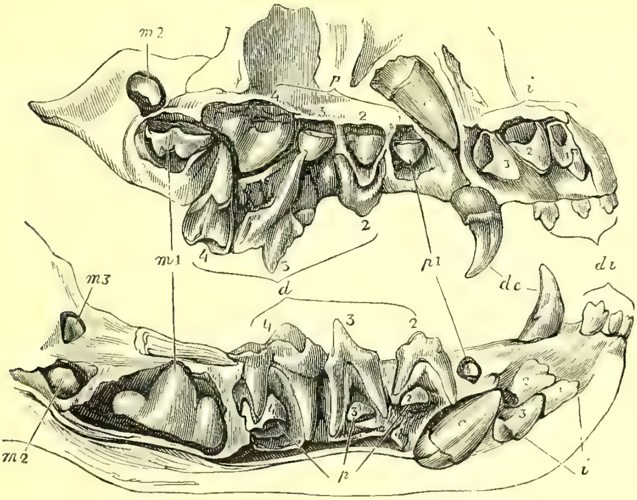
Fig. 581.

Deciduous and permanent dentition of the Bear (Ursus).

the other grinders in use are the deciduous molars, *d.* 2, *d.* 3, and *d.* 4; *d.* 2 will be displaced by *p.* 2, *d.* 3 by *p.* 3, and *d.* 4 by the tooth *p.* 4, which, notwithstanding its size and shape, Cuvier felt himself compelled to discard from the series of false molars, but which we now see is proved by its developmental relations to *d.* 4, as well as by its relative position and

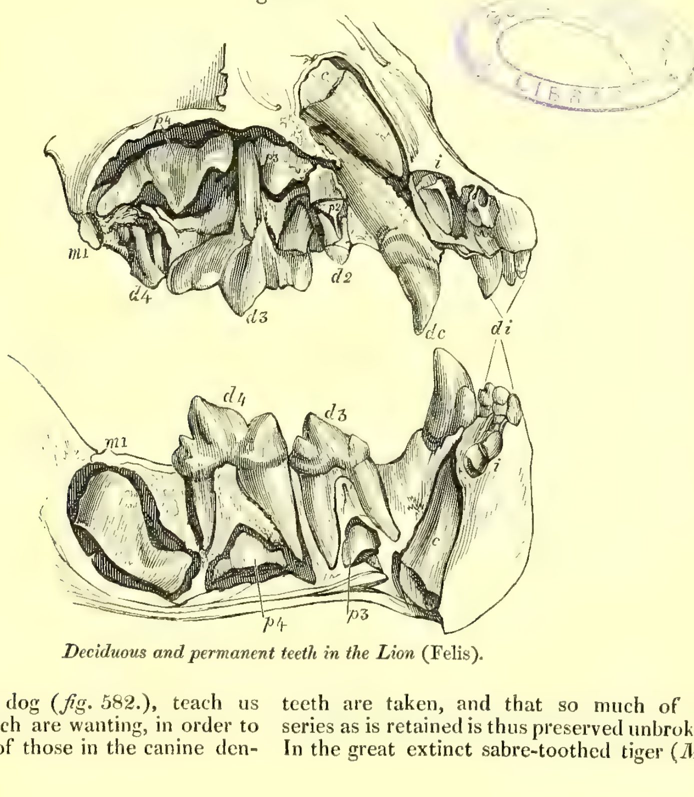
In the genus *Felis* (*fig.* 580.), the small permanent tubercular molar of the upper jaw, *m.* 1, has cut the gum before its analogue *d.* 4 of the deciduous series has been shed; but though analogous in function, this is not homologous with, or the precedent tooth to *m.* 1, but, as in the dog, to the great carnassially modified premolar, *p.* 4. In the lower jaw the tooth (*m.* 1), which is functionally analogous to the carnassial above, is also, as in the dog, the first of the true molar series, and the homotype of the little tubercular tooth (*m.* 1) above. And the homologies of the permanent teeth *p.* 4 above and *m.* 1 below, with those so symbolised in the dog (*fig.* 582.), teach us that the teeth which are wanting, in order to equal the number of those in the canine dentition, are *m.* 2 in the upper jaw, *m.* 2 and *m.* 3 in the lower jaw; *p.* 1 in the upper jaw, *p.* 1 and *p.* 2 in the lower jaw; thus illustrating the rule enuntiated above, that, when the molar series falls short of the typical number it is from the two extremes of such series that the teeth are taken, and that so much of the series as is retained is thus preserved unbroken. In the great extinct sabre-toothed tiger (*Ma-*

Fig. 582.



Deciduous and permanent teeth in the Dog (Canis).

Fig. 583.



Deciduous and permanent teeth in the Lion (Felis).

chairodus, *fig.* 580, VI.*), the series is still further reduced by the loss of *p.* 2 in the upper jaw.

That the student may test for himself the demonstration which the developmental characters above defined, yield of the true nature and homologies of the feline dentition, — the most modified of all in the terrestrial Carnivora, he is recommended to compare with nature the following details of the appearance and formation of the teeth in the common cat. In this species the deciduous incisors *d. i.* begin to appear between two and three weeks old; the canines *d. c.* next, and then the molars *d. m.* follow, the whole being in place before the sixth week. After the seventh month they begin to fall in the same order; but the lower sectorial molar *m.* 1, and its tubercular homotype above (*m.* 1) appear before *d.* 2, *d.* 3, and *d.* 4 fall. The longitudinal grooves are very faintly marked in the deciduous canines. The first deciduous molar (*d.* 2), in the upper jaw is a very small and simple one-fanged tooth; it is succeeded by the corresponding tooth of the permanent series, which answers to the second premolar (*p.* 2) of the hyæna and dog. The second deciduous molar (*d.* 3) is the sectorial tooth; its blade is trilobate, but both the anterior and posterior smaller lobes are notched, and the internal tubercle, which is relatively larger than in the permanent sectorial, is continued from the base of the middle lobe, as in the deciduous sectorial of the dog and hyæna; it thus typifies the form of the upper sectorial, which is retained in the permanent dentition of several Viverrine and Musteline species. The third or internal fang of the deciduous sectorial is continued from the inner tubercle, and is opposite the interspace of the two outer fangs. The Musteline type is further adhered to by the young Feline in the large proportional size of its deciduous tubercular tooth, *d.* 4. In the lower jaw, the first milk-molar (*d.* 3) is succeeded by a tooth (*p.* 3) which answers to the third lower premolar in the dog and civet. The deciduous sectorial (*d.* 4), which is succeeded by the premolar (*p.* 4), answering to the fourth in the dog, has a smaller proportional anterior lobe, and a larger posterior talon, which is usually notched; thereby approaching the form of the permanent lower sectorial tooth in the *Mustelidæ*.

In the article Carnivora (vol. i. p. 478.), the remarks on the teeth are limited chiefly to their physiological adaptations. A description of some of their more remarkable structures will here be given, according to the idea of the nature of the teeth above developed. The dental formula of the dog, jackal, wolf, and fox, is illustrated in *fig.* 580, III. Canis.

* *Machairodus*, from μάχαιρα, a sabre; and ὀδοὺς, a tooth. This generic name was imposed by Dr. Kaup on the extinct animal which was armed with canine teeth, like that figured in *fig.* 580, VI. Such teeth, long, compressed, falciform, sharp-pointed, and with anterior and posterior finely-serrated edges, were first discovered in tertiary strata in Italy and Germany, and were referred by Cuvier to a species of bear, under the name of *Ursus cultridens*. Fossil canines of this genus have been found in Kent's Hole cave, Torquay.

In the *Megalotis*, or Long-eared Fox (*Otocyon*, Licht.), the deviation from the typical dentition of the *Canidæ* is effected by excess of development; two additional true molars being present on each side of the upper, and one on each side of the lower jaw, in the permanent series of teeth; and an approach is made by the modified form of the sectorial molar and of some of the other teeth to the dentition of the *Viverridæ*. This family of Carnivora, which comprehends the Civets, Genets, Ichneumons, Musangs, Surikates, and Mangues, is characterised, with few exceptions, by the following formula: — *i.* $\frac{3-3}{3-3}$; *c.* $\frac{1-1}{1-1}$; *p.* $\frac{4-4}{4-4}$; *m.* $\frac{2-2}{2-2}$: = 40. It differs from that of the genus *Canis* by the absence of a tubercular tooth (*m.* 3) on each side of the lower jaw; but, in thus making a nearer step to the typical carnivorous dentition, the *Viverridæ*, on the other hand, recede from it by the less trenchant and more tubercular character of the sectorial teeth, as is shown in the figures of the teeth of the *Viverra indica*, in my "Odontography," pl. 126. figs. 1, 2, and 3.

The canines are more feeble, and their crowns are almost smooth; the premolars, however, assume a formidable size and shape in some aquatic species, as those of the sub-genus *Cynogale*, in which their crowns are large, compressed, triangular, sharp-pointed, with trenchant and serrated edges, like the teeth of certain sharks, (whence the name *Squalodon*, proposed for one of the species), and well adapted to the exigencies of quadrupeds subsisting principally on fish: the opposite or obtuse, thick form of the premolars is manifested by some of the Musangs, as *Paradoxurus auratus*. The upper sectorial tooth, *p.* 4, is characterised by having its inner tubercle larger, the middle conical division of the blade thicker, and the posterior one smaller than in the genus *Canis*. This tooth advances to beneath the ant-orbital foramen in the Musangs (*Paradoxurus*): it is situated farther back in the Civets and Genets, in which the blade of the sectorial is sharper. This shows that relative position to the zygomatic or molar process of the maxillary is not a good character.

In the lower jaw the sectorial tooth (*m.* 1) manifests its true molar character by the presence of an additional pointed lobe on the inner side of the two lobes forming the blade at the fore-part of the crown: the posterior, low, and large lobe of the tooth being also tri-tuberculate, as in the dog. The last molar (*m.* 2) has an oval crown with four small tubercles, resembling the penultimate lower molar in the dog, with which it corresponds.

The deciduous dentition consists, in the Viverrine family, of: incisors $\frac{3-3}{3-3}$; canines $\frac{1-1}{1-1}$; molars $\frac{3-3}{3-3}$: = 28. If the first permanent premolar has any predecessor, it must be rudimental and disappear early in both jaws; the second premolar displaces the first normally developed deciduous molar; the third upper premolar displaces and succeeds the deciduous sectorial, which has a sharper and more compressed blade, and a relatively smaller internal tubercle, than the permanent sectorial. This tooth displaces the last deciduous molar, which is a tubercular tooth, resembling in form the first of the two upper permanent tuberculars; these coming into place without pushing out any predecessors, enter into the category of true molar teeth. In the lower jaw the third premolar displaces the deciduous sectorial, which has three trenchant lobes and a relatively smaller posterior talon than the permanent sectorial. The fourth premolar displaces the third or tubercular milk-molar. The permanent sectorial and tubercular molars displace no predecessors, and are therefore *m.* 1 and *m.* 2.

The first premolar, *p.* 1, is not developed at any period in the Mangues (*Crossarchus*), the Suricates (*Ryzæna*), or the *Mangusta paludinosa*; these Viverrines, therefore, retain throughout life more of the immature characters of the family, and in the same degree approach in the numerical characters of their dentition to the more typical Carnivora.

The alternate interlocking of the crowns of the teeth of the upper and lower jaws, which is their general relative position in the Carnivora, is well marked in regard to the premolars of the *Viverridæ* (*fig.* 580, IV.): as the lower canine is in front of the upper, so the first lower premolar rises into the space between the upper canine and first upper premolar; the fourth lower premolar in like manner fills the space between the third upper premolar (*p.* 3) and the sectorial tooth (*p.* 4), playing upon the anterior lobe of the blade of that tooth which indicates by its position, as by its mode of succession, that it is the fourth premolar of the upper jaw. The first true molar below, modified as usual in the *Carnivora* to form the lower sectorial, sends the three tubercles of its anterior part to fill the space between the sectorial (*p.* 4) and the first true molar (*m.* 1) above. In the Musangs the lower sectorial is in more direct opposition to its true homotype, the first tubercular molar in the upper jaw; and these Indian *Viverridæ* (*Paradoxuri*) are the least carnivorous of their family, their chief food consisting of the fruit of palm-trees, whence they have been called "Palm-cats."

Hyæna.—The dentition of this genus presents a nearer approach to the strictly carnivorous type by the reduction of the tubercular molars to a single minute tooth on each side of the upper jaw, the inferior molars being all conical or sectorial teeth: the molar teeth in both jaws are larger and stronger, and the canines smaller in proportion than in the Feline species, from the formula of which the dentition of the hyæna differs numerically only in the retention of an additional premolar tooth, *p.* 1 above and *p.* 2 below, on each side of both jaws. The dental formula of the genus *Hyæna* is:—$in.\ \frac{3-3}{3-3},\ c.\ \frac{1-1}{1-1},\ pm.\ \frac{4-4}{3-3},\ m.\ \frac{1-1}{1-1} := 34.$ The crowns of the incisors form almost a straight tranverse line in both jaws, the exterior ones, above, being much larger than the four middle ones, and extending their long and thick inserted base further back: the crown of the upper and outer incisor (*i.* 3.) is strong, conical, recurved, like that of a small canine, with an anterior and posterior edge, and a slight ridge along the inner side of the base. The four intermediate small incisors have their crown divided by a transverse cleft into a strong anterior, conical lobe, and a posterior ridge, which is notched vertically; giving the crown the figure of a trefoil. The lower incisors gradually increase in size from the first to the third; this and the second have the crown indented externally; but they have not the posterior notched ridge like the small upper incisors; the apex of their conical crown fits into the interspace of the three lobes of the incisor above. The canines have a smooth convex exterior surface, divided by an anterior and posterior edge from a less convex inner side: this surface is almost flat and of less relative extent in the inferior canines. The first premolar above (*p.* 1) is very small, with a low, thick, conical crown: the second presents a sudden increase of size, and an addition of a posterior and internal basal ridge to the strong cone. The third premolar exhibits the same form on a still larger scale, and is remarkable for its great strength. The posterior part of the cone of each of these premolars is traversed by a longitudinal ridge. The fourth premolar is the carnassial tooth, and has its long blade divided by two notches into three lobes, the first a small thick cone, the second a long and compressed cone, the third a horizontal sinuous trenchant plate: a strong triedral tubercle is developed from the inner side of the base of the anterior part of the crown. The single true molar of the upper jaw (*m.* 1) is a tubercular tooth of small size: transversely oblong in the *Hyæna vulgaris* and *H. fusca*; smaller and sub-circular in the *Hyæna crocuta*; still smaller and implanted by a single fang in the *Hyæna spelæa*: in all the existing species of Hyæna it has two fangs. The first premolar of the lower jaw (*p.* 2) fits into the interspace between the first and second premolars above, and answers, therefore, to the second lower premolar in the *Viverridæ*: it is accordingly much larger than the first (*p.* 1) above; it has a ridge in the fore-part of its cone, and a broad basal talon behind. The second (*p.* 3) is the largest of the lower premolars, has an anterior and a posterior basal ridge, with a vertical ridge ascending upon the fore as well as the back part of the strong rounded cone: the third premolar (*p.* 4.) is proportionably less in the *Hyæna crocuta* than in the *H. vulgaris*: its posterior ridge is developed into a small cone; the last tooth (*m.* 1) is the sectorial, and consists almost entirely of a blade divided by a vertical fissure into two sub-equal compressed pointed lobes: the points are less produced than in the Felines, but the lower sectorial of the hyæna is better distinguished by the small posterior basal talon, from which a ridge is continued along the inner side of the base, and is slightly thickened at the fore-part of the crown. According to the relative position of the crowns of the premolars the third below ought to be the last, being analogous to the fourth in the *Viverridæ*, and the sectorial should be first true molar: we shall find this view confirmed by the test of the mode of succession of the permanent teeth. But the mode of implantation of the premolar and molar teeth may first be noticed. The first upper premolar has but one fang; the second and third have each two; the sectorial tooth has three, the two anterior ones on the same tranverse line, the inner one supporting the tubercle. The lower premolars and sectorial have each two fangs, there being none truly answering to the first above: the anterior root of the lower (*p.* 1) sectorial tooth is very strongly developed in the great extinct Cave-Hyæna.

The deciduous teeth consist of:—$i. \frac{3-3}{3-3}$, $c. \frac{1-1}{1-1}$, $m. \frac{3-3}{3-3}$, = 28. The figure of the skull of the young *Hyæna crocuta* in the posthumous edition of the "Ossemens Fossiles," 8vo. 1836, pl. 190, fig. 3, shows that stage when the correspondence with the formula of the genus *Felis* is completed by the appearance, in the upper jaw, of a small premolar in the interspace between the canine and first molar of the deciduous series: but this appearance is due to the apex of the first permanent premolar which cuts the gum before any of the normal deciduous teeth are shed: whether it is preceded, as in the dog, by a deciduous germ-tooth in the fœtus, I know not. The first normal deciduous molar is two-fanged, and has a more compressed and consequently more carnivorous crown than that of the second permanent premolar by which it is succeeded. The second deciduous molar is the sectorial tooth: the inner tubercle is continued from the base of the middle lobe, and thus resembles the permanent sectorial of the Glutton (*Gulo*) and many other *Mustelidæ;* the deciduous tubercular molar is relatively larger than in the adult *Hyæna*, and offers another feature of resemblance to the permanent dentition of the Glutton. It is also worthy of remark that the exterior incisor of the upper jaw is not only absolutely, but relatively smaller in the immature than in the adult dentition of the hyæna, and again illustrates the resemblance to the more common type of dentition in the Carnivora.

The first and second deciduous molars below have more compressed conical crowns than their successors: the third deciduous molar is the sectorial tooth, and, again, as in *Gulo*, has a better developed hinder tubercle than the permanent sectorial; it is not displaced by this tooth, but, as in other Carnivora, by a premolar of more simple character. The permanent sectorial is developed posteriorly, and rises, like other true molars, without displacing a deciduous predecessor.

The permanent dentition of the *Hyæna*, as of other genera or families of the Carnivora, assumes those characteristics which adapt it for the peculiar food and habits of the adult, and mark the deviation from the common type, which always accompanies the progress to maturity. The most characteristic modification of this dentition is the great size and strength of the molars as compared with the canines, and more especially the thick and strong conical crowns of the second and third premolars in both jaws, the base of the cone being belted by a strong ridge which defends the subjacent gum.* This form of tooth is especially adapted for gnawing and breaking bones, and the whole cranium has its shape modified by the enormous development of the muscles which work the jaws and teeth in this operation.† Adapted to obtain its food from the coarser parts of animals which are left by the nobler beasts of prey, the hyæna chiefly seeks the dead carcass, and bears the same relation to the lion which the vulture does to the eagle. In consequence of the quantity of bones which enter into its food, the excrements consist of solid balls of a yellowish white colour, and of a compact earthy fracture. Such specimens of the substance, known in the old *Materia Medica* by the name of "album græcum," were discovered by Dr. Buckland in the celebrated ossiferous cavern at Kirkdale. They were recognised at first sight by the keeper of a menagerie, to whom they were shown, as resembling both in form and appearance the fœces of the spotted Hyæna; and, being analysed by Dr. Wollaston, were found to be composed of the ingredients that might be expected in fœcal matter derived from bones, viz. phosphate of lime, carbonate of lime, and a very small proportion of the triple phosphate of ammonia and magnesia. This discovery of the coprolites of the hyæna formed, perhaps, the strongest of the links in that chain of evidence by which Dr. Buckland proved that the cave at Kirkdale, in Yorkshire, had been, during a long succession of years, inhabited as a den by hyænas, and that they dragged into its recesses the other animal bodies, whose remains, splintered and bearing marks of the teeth of the hyæna, were found mixed indiscriminately with their own.

* An eminent civil engineer, to whom I showed the jaw of a hyæna, observed that the strong conical tooth, with its basal ridge, was a perfect model of a hammer for breaking stones for roads.

† "The strength of the hyæna's jaw is such that, in attacking a dog, he begins by biting off his leg at a single snap." Buckland, "Reliquiæ Diluvianæ," p. 23.

The dentition of the Weasel tribe (*Mustelidæ*) is illustrated (in *fig.* 580, IV.) by that of the Otter, *Mustela Lutra* of Linnæus, and which is essentially a great aquatic Weasel or Polecat; its dental formula is $i.\ \frac{3-3}{3-3}$, $c.\ \frac{1-1}{1-1}$, $p.\ \frac{4-4}{3-3}$, $m.\ \frac{1-1}{2-2}$: = 36. In the Martin cats (*Mustela martes*, L.), the little homotype of *p.* 1 above is present in the lower jaw; in the bloodthirsty stoats and weasels, *p.* 1 is absent in both jaws; as it is likewise in the great sea-otter (*Enhydra*), in which also the two middle incisors are wanting in the lower jaw. In this animal the second premolar (*p.* 3) has a strong obtuse conical crown, double the size of that of *p.* 2; the third premolar (*p.* 4) is more than twice the size of *p.* 3, and represents the upper carnassial or sectorial strangely modified; the two lobes of the blade being hemispheric tubercles. The last tooth, *m.* 1, has a larger crown than the sectorial, and is of a similar broad crushing form. In the lower jaw the molar series are not separated by any interspace: the first and second premolars have oblique obtuse conical crowns. The third premolar (*p.* 4) is more than twice the size of the second (*p.* 3) and supports a large anterior hemispheric protuberance with a small internal tubercle and a posterior basal ridge. The first true molar has an oblong quadrate crown with an anterior small tubercle, a larger and more prominent inner one, and the rest of the broad horizontal surface undulating. The second true molar has a transversely elliptical crown depressed in the centre. When the teeth are in apposition, the anterior third of the first true molar below is applied to the inner tubercle of the last premolar above; the rest of its crown plays upon that of its homotype, the first true molar in the upper jaw, leaving a small part of that tooth to receive the appulse of the second true molar below, which has no corresponding tooth in the upper jaw.

The *Mustelidæ* present great constancy in regard to the number of their true molar teeth; with one exception, the Ratel (*Mellivora*), in which *m.* 2 is absent below, they have one true molar on each side of the upper jaw, and two on each side of the lower jaw; the second of these has always a broad tubercular crown, like the one above. The upper true molar is supported by one inner, and sometimes by one (*Putorius*, *Gulo*), sometimes two (*Mustela*, *Lutra*, *Melphitis*), outer fangs. The second true molar below is also tubercular, but has a single fang. The crown of the first true molar below offers many gradations from the sectorial type, as manifested in *Putorius* and *Gulo*, to the tubercular type, as in the Taira, Ratel, and sea-otter. The principal varieties occur, as usual, in the comparatively less important premolars: in the Martins and Gluttons, they are as numerous as in the dog; the first, in both jaws, being implanted by a single fang; the rest by two, with the exception of the last above, which has three roots. In the otter, we find the first premolar removed from the lower jaw; and the second (now the first) shows its true homology by its double implantation, as well as by the position of its crown behind the first in the upper jaw (*p.* 1). In the Stoats, Skunks, and Ratels, the premolar series is further reduced by the loss of the anterior tooth (*p.* 1) in both jaws, and by the diminution of the size of *p.* 2, which thus becomes the first in both jaws, and which is also now implanted by a single fang. In a South American Skunk, the second premolar disappears in the upper jaw, leaving there only the homologues of the third and fourth of the typical formula, *p.* 4 being always the sectorial in the *Mustelidæ*, as in other terrestrial Carnivora. This tooth, under all its modifications, retains the blade with the lobe, corresponding to the middle one in the feline sectorial, generally well developed and sharp-pointed; the differences are principally manifested by the proportions of the inner tubercle, and the relative size of the third root supporting it. But the upper sectorial, being a premolar, and therefore requiring less modification of the crown to adapt it for its special functions, manifests a more limited extent of variety than the lower sectorial, which, being a true molar, requires greater modification of the typical form of its crown to fit it for playing upon the sectorial blade of *p.* 4 above.

Melidæ.—In this sub-family I comprise the European Badger (*Meles*), the Indian Badger (*Arctonyx*), and the American Badger (*Taxidea*); which, with respect to their dentition, stand at the opposite extreme of the *Mustelidæ* to that occupied by the predaceous Weasel, and manifest the most tuberculate and omnivorous character of the teeth. The formula is:—$i.\ \frac{3-3}{3-3}$; $c.\ \frac{1-1}{1-1}$; $p.\ \frac{3-3}{4-4}$; $m.\ \frac{1-1}{2-2}$: = 30.

The canines are strongly developed, well pointed, with a posterior trenchant edge; they are more compressed in *Arctonyx* than in *Meles*. The first lower premolar (*p.* 1) is very small, single-fanged, and, generally, soon lost. The first above, corresponding with the second in the dog, is also small, and implanted by two connate fangs. The second upper premolar (*p.* 3) has a larger, but simple, sub-compressed conical crown, and is implanted by two fangs: the third (*p.* 4) repeats the form of the second on a larger scale, with a better developed posterior talon, and with the addition of a tri-tuberculate low flat lobe, which is supported by a third fang: the outer pointed and more produced part of this tooth represents the blade of the sectorial tooth and the entire crown of the antecedent premolars. The true molar in *Meles* (*m.* 1) is of enormous size compared with that of any of the preceding Carnivora: it has three external tubercles, and an extensive horizontal surface traversed longitudinally by a low ridge, and bounded by an internal belt, the *cingulum* of Illiger: this tooth has a similarly shaped, but relatively smaller, crown in *Arctonyx*.* The second premolar below (*p.* 2) is commonly the first, through the early loss of the minute one in front; its fangs are usually connate, as in its homotype above. The third and fourth premolars slightly increase in size, have simple compressed conical crowns, and two fangs each. The first true molar below (*m.* 1) now retains little of its sectorial character, the blade being represented only by the two anterior small, compressed pointed lobes; behind these, the crown expands into an oval grinding surface, narrower in *Arctonyx* than in *Meles*, supporting three tubercles and a posterior tuberculate ridge: it has generally two principal roots and a small intermediate accessory fang, as in the otter. The second molar (*m.* 2), which terminates the series below, is of small size, and has a rounded flat crown, depressed in the centre, and with two small external tubercles; its two short fangs are connate. In the Labrador Badger, the last premolar has a larger relative size, the part corresponding with the blade of the sectorial, is sharper and more produced, and the internal tubercle has two lobes; the succeeding molar tooth is reduced in size, and its crown presents a triangular form. The first true molar below has its sectorial lobes better developed: these differences give the North American badgers a more carnivorous character than is manifested by the Indian or European species.

Sub-Ursidæ.—In other allied genera, which, like the badgers, have been grouped, on account of the plantigrade structure of their feet, with the bears, a progressive approximation is made to the type of the dentition of the Ursine species. The first true molar below soon loses all its sectorial modification, and acquires its true tubercular character: and the last premolar above becomes more directly and completely opposed to its homotype in the lower jaw. The Racoon (*Procyon* †) and the Coati (*Nasua*) present good examples of these transitional modifications; they have the complete number of premolar teeth, the dental formula being, $i.\frac{3-3}{3-3}$, $c.\frac{1-1}{1-1}$, $p.\frac{4-4}{4-4}$, $m.\frac{2-2}{2-2}:=40$. The development of the inner part of the crown of the last upper premolar, which constitutes the tubercle of the sectorial tooth, now produces two tubercles on a level with the outer ones which represent the blade; and the opposite premolar below (*p.* 4), which is the true homotype of the modified sectorial above, begins to acquire a marked increase of breadth and accessory basal tubercles. All the lower premolars, as well as the true molars, have two fangs; the three first premolars above have two fangs, the fourth has three, like the two true molars above.

The dental formula of the Indian Benturong (*Arctictis*) and Kinkajou (*Cercoleptes*) is $i.\frac{3-3}{3-3}$, $c.\frac{1-1}{1-1}$, $p.\frac{3-3}{3-3}$, $m.\frac{2-2}{2-2}:=36$.

Phocidæ.—We have seen a tendency to deviate from the ferine number of the incisors in the most aquatic and piscivorous of the Musteline quadrupeds, viz. the sea-otter (*Enhydra*), in which species the two middle incisors of the lower jaw are not developed in the permanent dentition. In the family of true seals, the incisive formula is further reduced, in some species even to zero in the lower jaw, and it never exceeds $\frac{3-3}{2-2}$. All the *Phocidæ* possess powerful canines; only in the aberrant walrus (*Trichechus*) are they absent in the lower jaw, but this is compensated by the singular excess of development which they manifest in the upper jaw. In the pinnigrade, as in the plantigrade, family of Carnivores we find the teeth which correspond to true molars more numerous than in the digitigrade species, and even occasionally rising to the typical number, three on each side; but this, in the seals, is manifested in the upper and not, as in the bears, in the lower jaw. The entire molar series usually includes five, rarely six teeth on each side of the upper jaw, and five on each side of the lower jaw, with crowns, which vary little in size or form in the same individual; they are supported in some genera, as the Eared Seals (*Otariæ*) and Elephant Seals (*Cystophora**), by a single fang; in other genera † by two fangs, which are usually connate in the first or second teeth; the fang or fangs of both incisors, canines and molars, are always remarkable for their thickness, which commonly surpasses the longest diameter of the crown. The crowns are most commonly compressed, conical, more or less pointed, with the "cingulum" and the anterior and posterior basal tubercles more or less developed; in a few of the largest species they are simple and obtuse, and particularly so in the walrus, in which the molar teeth are reduced to a smaller number than in the true seals.‡ In these the line of demarcation between the true and false molars is very indefinitely indicated by characters of form or position; but, according to the instances in which a deciduous dentition has been observed, the first three permanent molars in both jaws succeed and displace the same number of milk molars, and are consequently *premolars;* occasionally, in the seals with two-rooted molars, the more simple character of the premolar teeth is manifested by their fangs being connate, and in the *Stenorhynchus serridens* the more complex character of the true molars is manifested in the crown. There is no special modification of the crown of any tooth by which it can merit the name of a

* See Odontography, pl. 128, *fig.* 13, *m.* 1.
† Ib. pl. 129, *fig.* 7. ‡ Ib. *figs.* 8—13.

* Odontography, pl. 132, *fig.* 7.
† Ib. *figs.* 1—4.
‡ The relation of *Trichechus* to the *Phocidæ* is analogous to that of *Machairodus* to the *Felidæ*, and also, in the simplification of the molars, to that of *Proteles* to *Canidæ*.

"sectorial" or "carnassial;" but we may point with certainty to the third molar above and the fourth below as answering to those teeth which manifest the sectorial character in the terrestrial Carnivora.

The coadaptation of the crowns of the upper and lower teeth is more completely alternate than in any of the terrestrial Carnivora, the lower tooth always passing into the interspace anterior to its fellow in the upper jaw. In the genus *Phoca* proper (*Calocephalus*, Cuv.) typified by the common seal (*Ph. vitulina*), the dental formula is, $i.\ \frac{3-3}{2-2}$, $c.\ \frac{1-1}{1-1}$, $p.\ \frac{3-3}{3-3}$, $m.\ \frac{2-2}{2-2}:=34$. The forms and proportions of these teeth are shown in Pl. 132, *fig.* 1., of my "Odontography." The first tooth above and below presents a complete confluence of the fangs; they are separated from the second above; but below they sometimes do not become free before the fourth, and sometimes the two roots are distinct in the third and second molars. In the *Phoca anellata* Nills., the principal cusp of the molar teeth is complicated with anterior and posterior smaller cusps, sometimes one in number in the upper molars; the anterior accessory cusp is sometimes wanting in the first, and is rudimentary in the rest; but usually there are two small cusps behind the principal one, and in the three or four posterior molars in the lower jaw there are sometimes two small cusps before and two behind the principal one.*

In the *Phoca caspica* the upper molars have commonly one accessory cusp before and one behind the principal lobe; the lower molars have one accessory cusp before and two behind.

In the *Phoca grœnlandica* the upper molars have no anterior basal cusp and only one behind; the lower molars have two cusps behind and one in front, except the first, which resembles that above, and, like it, has connate fangs.

The condition of the molar teeth is nearly the same in the *Phoca barbata*, but the crowns are rather thicker and stronger, and the three middle ones above have two posterior basal cusps feebly indicated, the same being more strongly marked in the four last molars below.

The following genera of seals with double-rooted molars (*Pelagius* and *Stenorhynchus*) have four incisors above as well as below, *i. e.* $\frac{2-2}{2-2}$. An upper view of the molar teeth in the Hooded Seal of the Mediterranean (*Pelagius monachus*) is given in my Odontography, Pl. 132. *fig.* 3., as when they are worn down in an old specimen; the crowns are thick, obtuse, sub-compressed, with a well developed cingulum, a principal lobe and an anterior and posterior accessory basal lobule; the fangs are connate in the first tooth both above and below.

The allied sub-genus (*Ommatophoca*) of seals of the southern hemisphere has six molar teeth on each side of the upper, and five on each side of the lower jaw, with the principal lobe of the crown more incurved. The two first molars above are closely approximated, but this may prove to be a variety.

In the *Stenorhynchus* the jaws are more slender and produced, and the molar teeth are remarkable for the long and slender shape of the principal lobe, and of the accessory basal cusps. The incisors have sharp conical recurved crowns, like the canines, and the external ones in the upper jaw are intermediate in size between the canines and the middle incisors.

In the *Stenorhynchus leptonyx* each molar tooth in both jaws is trilobed, the anterior and posterior accessory curving towards the principal one, which is bent slightly backwards; all the divisions are sharp-pointed, and the crown of each molar thus resembles the trident or fishing-spear; the two fangs of the first molar in both jaws are connate. In *Stenorhynchus serridens* the three anterior molars on each side of both jaws are four-lobed, there being one anterior and two posterior accessory lobes; the remaining posterior molars (true molars) are five-lobed, the principal cusp having one small lobe in front, and three developed from its posterior margin; the summits of the lobes are obtuse, and the posterior ones are recurved like the principal lobe. Sometimes the third molar below has three instead of two posterior accessory lobes. Occasionally, also, the second, as well as the first molar above, has it fangs connate; but the essentially duplex nature of the seemingly single fang, which is unfailingly manifested within by the double pulp-cavity, is always outwardly indicated by the median longitudinal opposite indentations of the implanted base. These slight and unessential varieties, presented by the specimens of the Saw-toothed Sterrink (*Stenorhynchus serridens*) brought home by the enterprising Naturalist of Sir J. Ross's Antarctic expedition, accord with the analogous varieties noticed by the best observers of the seals of our neighbouring seas, as, for example, Nillson.

The Grey Seal (*Halichœrus gryphus*) of our own seas begins, by the extension of the connate condition of the two roots through a greater proportion of the molar series, to manifest a transition to the family of seals with true single-rooted molars; the formula of this genus is, $i.\ \frac{3-3}{2-2}$, $c.\ \frac{1-1}{1-1}$, $p.\ \frac{3-3}{3-3}$ $m.\ \frac{2-2}{2-2}:=34$. The four middle upper incisors are close set, with pointed recurved crowns; the lateral ones are much larger and laniariform; the canines have moderate crowns, with a sharp ridge before and behind. The

* Nillson, in Wiegmann's Archiv. 1841, 313. I notice these varieties of the crown, in connection with analogous ones in the fangs of the teeth of the same species, to show the inadequacy of such characters as marks of subgeneric distinction.

crowns of the molar teeth are conical, sub-compressed longitudinally and finely grooved, with an anterior and posterior edge; those below have generally a slight notch at the fore and back part of the base. The first molars, both above and below, are the smallest, with a simple crown and a single ventricose fang; the second and third above, and the second, third, and fourth below, have two connate roots; the two roots are commonly distinct in the remaining posterior molars: all the roots are very thick.

In the genus *Otaria* the dental formula is, $i. \frac{3-3}{2-2}, c. \frac{1-1}{1-1}, p. \frac{3-3}{3-3}, m. \frac{3-3}{2-2} = 36.$ The two middle upper incisors are small, sub-compressed, with the crown transversely notched; the simple crowns of the four incisors below fit into these notches: the outer incisors above are much larger, with a long pointed conical crown, like a small canine. The true canine is twice as large as the adjoining incisor, and is rather less recurved. The molars have each a single fang; the crown is conical, sub-compressed, pointed; in the two last recurved, with a basal ridge or "cingulum," broadest within; but, in the *Otaria jubata*, the molars have a pointed cusp developed from the fore-part, and in the last two molars also from the back part of the crown. In some species, as the *Otaria lobata* (*Phoca lobata*, Fischer), the single molar is not developed in the upper jaw, and the outer incisors above are not so large: in this species a thick plicated cingulum belts the base of each molar and developes a small tubercle from its fore-part in the molars of the lower jaw; the crown of the last molar above is notched.

In the great proboscidian and hooded Seals (*Cystophora*), the incisors and canines still more predominate in size over the molars; but the incisors are reduced in number, the formula here is: $i. \frac{2-2}{1-1}, c. \frac{1-1}{1-1}, p. \frac{3-3}{3-3}, m. \frac{2-2}{2-2} := 30.$ All the molars are single-rooted, and all the incisors are laniariform. The two middle incisors above and the two below are nearly equal; the outer incisors above are larger. The canines are still more formidable, especially in the males; the curved root is thick and subquadrate. The crowns of the molar teeth are short, sub-compressed, obtuse; sometimes terminated by a knob and defined by a constriction or neck from the fang; the last is the smallest.

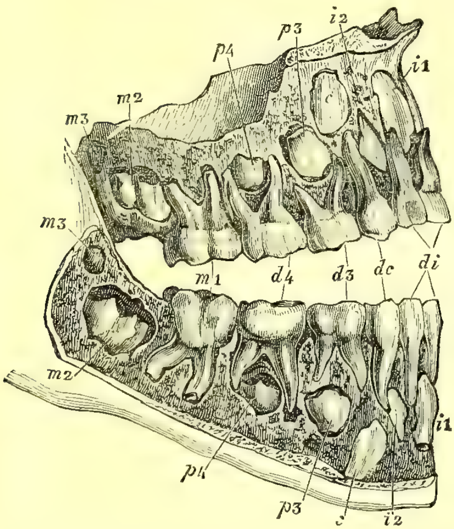
In the Walrus (*Trichechus rosmarus*), the normal incisive formula is transitorily represented in the very young animal, which has three teeth in each intermaxillary bone and two on each side of the fore-part of the lower jaw; they soon disappear, except the outer pair above, which remain close to the intermaxillary suture, on the inner side of the sockets of the enormous canines, and seem to commence the series of small and simple molars which they resemble in size and form. In the adult there are usually three molars or premolars on each side above, behind the permanent incisor, and four similar teeth on each side of the lower jaw; the anterior one passing into the interspace between the upper incisor and the first molar, and therefore being the homotype of the molar. In a young walrus's skull with canine tusks eight inches long, I have seen a fourth upper molar, (fifth including the incisor), of very small size, about a line in breadth, lodged in a shallow fossa of the jaw, behind the three persistent molars. The crowns of these teeth must be almost on a level with the gums in the recent head; they are very obtuse and worn obliquely from above down to the inner border of their base. The molars of the lower jaw are rather narrower from side to side than those above, and are convex or worn upon their outer side. Each molar has a short, thick, simple and solid root.

The canines are developed only in the upper jaw, but are of enormous size, descending and projecting from the mouth, like tusks, slightly inclined outwards and bent backwards; they present an oval transverse section, with a shallow longitudinal groove along the inner side, and one or two narrower longitudinal impressions upon the outer side; the base of the canine is widely open, its growth being uninterrupted.

The food of the walrus consists of sea-weed and bivalves; the molars are well adapted to break and crush shells; and fragments of a species of *Mya* have been found, with pounded sea-weed, in the stomach. The canine tusks serve as weapons of offence and defence, and to aid the animal in mounting and clambering over blocks of ice. For their composition and microscopic structure I must refer to my "Odontography," p. 511. *et seq.*

The precise determination of the teeth in the walrus and some other kinds of seals, still awaits the opportunity of examining very young specimens with the deciduous series, which is very early lost. When the clew is afforded by the opportunity of studying the development and succession of the teeth, it infallibly conducts us to the true knowledge of the nature, both of the teeth which are retained, and of those that are wanting to complete the typical number. We have availed ourselves of this in deciphering the much modified dentition of the genus *Felis;* and the same clew will guide us to a similar satisfactory knowledge of the nature and homologies of the teeth in the human species. The discovery, by the great poet Göthe, of the limits of the premaxillary bone in man leads to the determination of the incisors, which are reduced to two on each side of both jaws: the contiguous tooth shows by its shape, as well as position, that it is the canine, and the characters of size and shape have also served to divide the remaining five teeth in each lateral series into two bicuspids and three molars. In this instance, as in the dentition of the bear, the secondary characters conform with the essential ones. But since we have seen of how little value shape or size are, in the order Carnivora, in the determination of the exact homologies of the teeth, it is satisfactory to know that the more constant and important character of development gives the requisite certitude as to the nature of the so-called bicuspids in the human subject. In *fig.* 584., the condition of the

Fig. 584.



Deciduous and permanent teeth of a Child (Homo).

teeth is shown in the jaws of a child of about six years of age. The two incisors on each side (*di.*) are followed by a canine, *dc.*, and this by three teeth having crowns resembling those of the three molar teeth of the adult. In fact, the last of the three is the first of the permanent molars; it has pushed through the gum, like the two molars which are in advance of it, without displacing any previous tooth, and the substance of the jaw contains no germ of any tooth destined to displace it: it is therefore, by this character of its development, a true molar, and the germs of the permanent teeth, which are exposed in the substance of the jaw between the diverging fangs of the molars, *d.* 3 and *d.* 4, prove those molars to be temporary, destined to be replaced, and prove also that the teeth about to displace them are premolars. According, therefore, to the rule previously laid down, we count the permanent molar in place the first of its series (*m.* 1), and the adjoining premolar as the last of its series, and consequently the fourth of the typical dentition, or *p.* 4.

We are thus enabled, with the same scientific certainty as that whereby we recognise in the middle toe of the foot the homologue of that great digit which forms the whole foot and is encased by the hoof in the horse, to point to *p.* 4, or the second bicuspid in the upper jaw, and to *m.* 1, or the first molar in the lower jaw of man, as the homologues of the great carnassial teeth of the lion and tiger. We also conclude that the teeth which are wanting in man to complete the typical molar series, are the first and second premolars, the homologues of those marked *p.* 1 and *p.* 2 in the bear. The characteristic shortening of the maxillary bones required this diminution of the number of their teeth, as well as of their size, and of the canines more especially; and the still greater curtailment of the premaxillary bone is attended with a diminished number and an altered position of the incisors. One sees, indeed, in the carnivorous series, that a corresponding decrease in the number of the premolars is concomitant with the shortening of the jaws. Already in the *Mustelidæ*, (*fig.* 580., IV), *p.* 1 below is abrogated; in *Felis* also above, with the further loss of *p.* 2 in the lower jaw; the true molars being correspondingly reduced in these strictly flesh-eating animals, but taken away from the back part of their series.

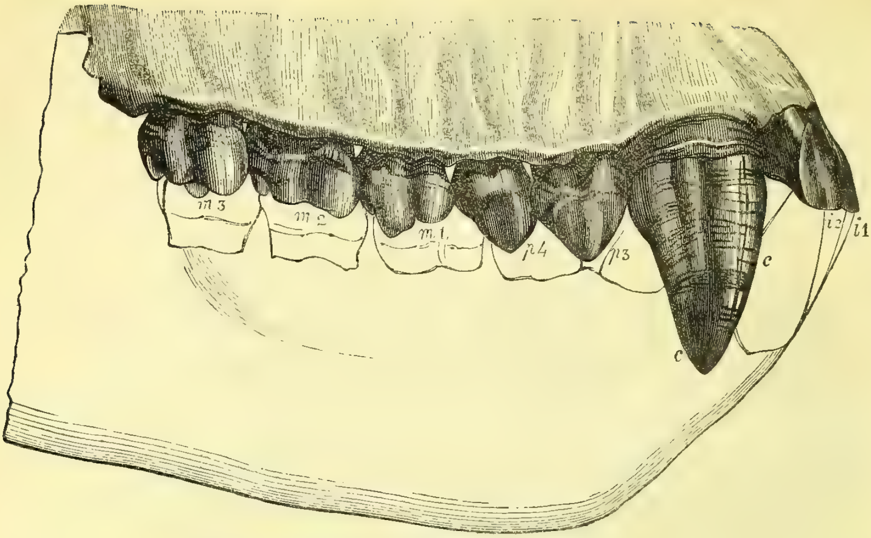
If we were desirous of further testing the soundness of the foregoing conclusions as to the nature of the teeth absent in the reduced dental formula of man, we ought to trace the mode in which the type is progressively resumed in descending from man through the order most nearly allied to our own.

Through a considerable part of the Quadrumanous series, *e. g.* in all the Old World genera above the Lemurs, the same number and kinds of teeth are present as in man; the first deviation being the disproportionate size of the canines and the concomitant break or "diastema" in the dental series for the reception of their crowns when the mouth is shut. This is manifested in both the Chimpanzees and Orangs, together with a sexual difference in the proportions of the canine teeth.

As the precise characteristics of the human dentition are best demonstrated by comparison with that brute species which is most nearly allied to Man, and makes the first step in the descending scale, I here subjoin the details of such a comparison, which is the more required since it is not touched upon in the article QUADRUMANA, and will be the more acceptable as one of its subjects is a species of Chimpanzee (*Troglodytes Gorilla*) *, unknown to science when that article was written, and which, so far as its organisation is known, is more anthropoid than even the docile and smaller species of Chimpanzee (*Troglodytes niger*). A side view of the teeth of a male, full-grown, but not aged, specimen of the great Chimpanzee is given of the natural size in *fig.* 585., and a view of the working surface of the whole series of the upper jaw in *fig.* 586. This dentition, though in all its principal characters strictly quadrumanous, yet, in the

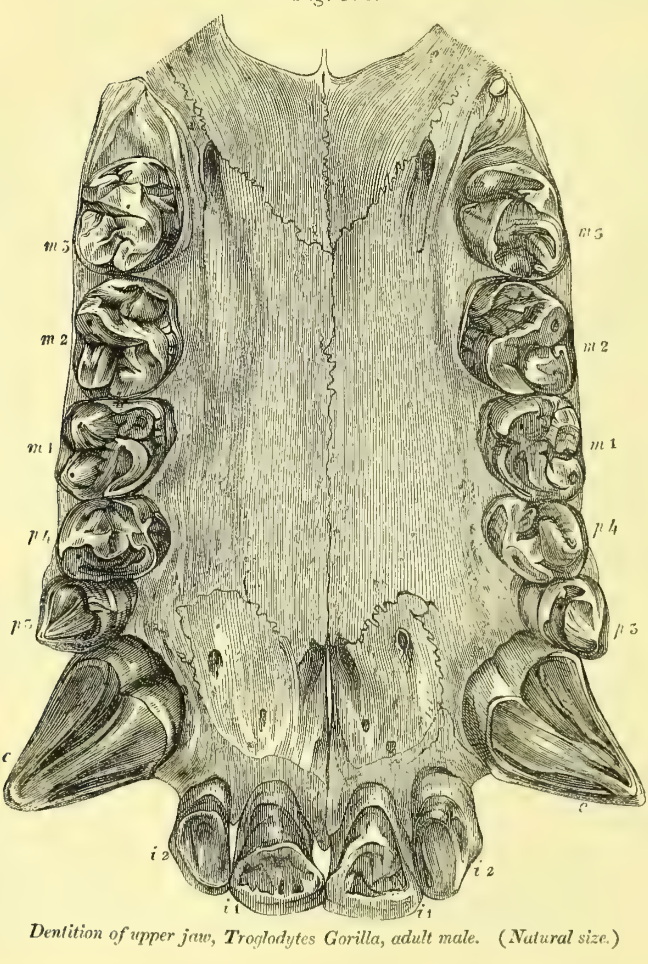
* Drs. Savage and Wyman, Boston Journal of Natural History, 1847; Owen, Transactions of the Zoological Society, vol. iii. p. 381 (February, 1848). M. F. Cuvier has not given a figure of the dentition of any species of Chimpanzee (*Troglodytes*). Believing with his brother, that the Orang (*Pithecus*, Geoffr.) made the nearest approach to man, the dentition of an immature *Pithecus Wurmbii* with one of the characteristically large permanent molars (*m.* 1) in place, immediately follows the plate of the human dentition in the "Dents des Mammifères," 8vo. pls. i. & ii.

Fig. 585.



Dentition of adult male, Troglodytes Gorilla. (Natural size.)

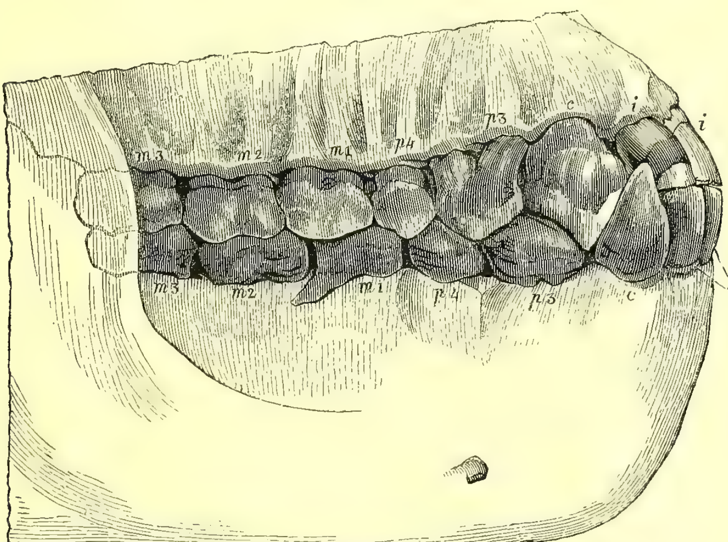
Fig. 586.



Dentition of upper jaw, Troglodytes Gorilla, adult male. (Natural size.)

minor particulars in which it differs from the dentition of the Orang, approaches nearer the human type. In the upper jaw the middle incisors (*fig.* 586, *i.* 1) are smaller, the lateral ones (ib. *i.* 2) larger than those of the Orang*; they are thus more nearly equal to each other; nevertheless the proportional superiority of the middle pair is much greater than in Man, and the proportional size of the four incisors both to the entire skull and to the other teeth is greater. Each incisor has a prominent posterior basal ridge, and the outer angle of the lateral incisors, *i.* 2, is rounded off as in the Orang. The incisors incline forwards from the vertical line as much as in the great Orang. Thus the characteristics of the human incisors are, in addition to their true incisive wedge-like form, their near equality teeth" *, when the mouth is closed, is applicable only to the female, and does not distinguish the Chimpanzees from the Orangs. In the male of the smaller Chimpanzee (*Troglodytes niger*) the upper canine is conical, pointed, but more compressed than in the Orang, and with a sharper posterior edge; convex anteriorly, becoming flatter at the posterior half of the outer surface, and concave on the corresponding part of the inner surface, which is traversed by a shallow longitudinal impression; a feeble longitudinal rising and a second linear impression divide this from the convex anterior surface, which also bears a longitudinal groove at the base of the crown. The canine is rather more than twice the size of that in the female. In the male *Gorilla* (*figs.* 585, 586.), the crown of the canine is

Fig. 587.



Dentition of adult female, Troglodytes Gorilla. (*Natural size.*)

of size, their vertical or nearly vertical position, and small relative size to the other teeth and to the entire skull. The diastema between the incisors and the canine on each side is as well marked in the male Chimpanzee as in the male Orang.† The crown of the canine (ib. *c.*), passing outside the interspace between the lower canine and premolar, extends in the male *Troglodytes Gorilla* a little below the alveolar border of the under jaw when the mouth is shut; the upper canine of the male *Troglodytes niger* likewise projects a little below that border; the seventh character, therefore, which I had formerly assigned to the genus, "apices of canines lodged in intervals of the opposite more inclined outwards: the anterior groove on the inner surface of the crown is deeper; the posterior groove is continued lower down upon the fang, and the ridge between the two grooves is more prominent than in the *Troglodytes niger*. Both premolars (*fig.* 586. *p.* 3 and *p.* 4) are bicuspid; the outer cusp of the first and the inner cusp of the second being the largest, and the first premolar consequently appearing the largest on an external view (*fig.* 585.). The difference is well marked in the female (*fig.* 587, *p.* 3, *p.* 4). The anterior external angle of the first premolar is not produced as in the Orang, which in this respect makes a marked approach to the lower *Quadrumana*. In Man, where the outer curve of the premolar part of the dental series is greater than the inner one, the outer cusps of both premolars are the largest; the alternating superiority of size in the Chimpanzee accords

* Compare *fig.* 586. with pl. xxxii. (*Pithecus Wurmbii*) and pl. xxxiv. (*Pith. Morio*), in vol. ii. Zool. Trans.

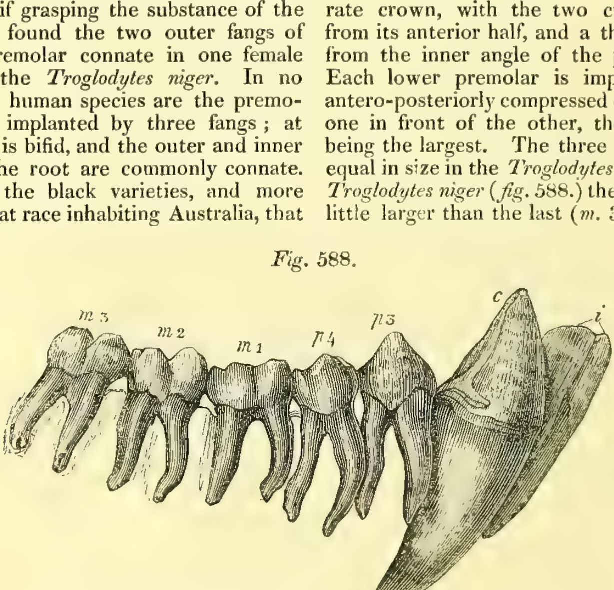
with, and contributes to, the straight line which the canine and premolars form with the true molars.

The true molars (*fig.* 586., *m.* 1, *m.* 2, *m.* 3) are quadricuspid, relatively larger in comparison with the bicuspids than in the Orang. In the first and second molars of both species of Chimpanzee a low ridge connects the antero-internal with the postero-external cusp, crossing the crown obliquely, as in Man. There is a feeble indication of the same ridge in the unworn molars of the Orang; but the four principal cusps are much less distinct, and the whole grinding surface is flatter and more wrinkled than in the Chimpanzee. In the *Troglodytes niger* the last molar is the smallest, owing to the inferior development of the two hinder cusps, and the oblique connecting ridge is feebly marked. In the *Troglodytes Gorilla* this ridge is as well developed as in the other molars, but is more transverse in position; and the crown of *m.* 3 is equal in size to that of *m.* 1 or *m.* 2, having the posterior outer cusp, and particularly the posterior inner cusp, more distinctly developed than in the *Troglodytes niger*. The repetition of the strong sigmoid curves which the unworn prominences of the first and second true molars present in Man, is a very significant indication of the near affinity of the Chimpanzee as compared with the approach made by the Orangs or any of the inferior *Quadrumana*, in which the four cusps of the true molars rise distinct and independently of each other. A low ridge girts the base of the antero-internal cusp of each of the upper true molars in the male Chimpanzee: it is less marked in the female. The premolars as well as molars are severally implanted by one internal and two external fangs, diverging but curving towards each other at their ends as if grasping the substance of the jaw. I have found the two outer fangs of the second premolar connate in one female specimen of the *Troglodytes niger*. In no variety of the human species are the premolars normally implanted by three fangs; at most the root is bifid, and the outer and inner divisions of the root are commonly connate. It is only in the black varieties, and more particularly that race inhabiting Australia, that I have found the wisdom tooth, *m.* 3, with three fangs as a general rule; and the two outer ones are more or less confluent.

In the lower jaw of the great Chimpanzee the lateral incisors are broader than the middle ones, although they are smaller relatively than in the *Troglodytes niger;* they are larger and less vertically implanted than in Man. The lower canines are two inches and a half in length, including the root; the enamelled crown is an inch and a quarter in length, and nearly an inch across the base; it is conical and trihedral; the outer and anterior surface is convex, the other two surfaces are flattened or subconcave, and converging to an almost trenchant edge directed inwards and backwards; a ridge separates the convex from the antero-internal flat surface; both this and the posterior surface show slight traces of a longitudinal rising at their middle part. The lower canine of the male shows the same relative superiority of size as the upper one compared with that in the female in both species of Chimpanzee. The canine almost touches the incisor, but is separated by a diastema one line and a half broad from the first premolar. This tooth (*p.* 3) is larger externally than the second premolar, and is three times the size of the human first premolar (*p.* 3); it has a subtrihedral crown, with the anterior and outer angle produced forwards, slightly indicating the peculiar feature of the same tooth in the Baboons, but in a less degree than in the Orang. The summit of the crown of *p.* 3 terminates in two sharp trihedral cusps, the outer one rising highest, and the second cusp being feebly indicated on the ridge extending from the inner side of the first; the crown has, also, a thick ridge at the inner and posterior part of its base. The second premolar (*p.* 4) has a subquadrate crown, with the two cusps developed from its anterior half, and a third smaller one from the inner angle of the posterior ridge. Each lower premolar is implanted by two antero-posteriorly compressed divergent fangs, one in front of the other, the anterior fang being the largest. The three true molars are equal in size in the *Troglodytes Gorilla;* in the *Troglodytes niger* (*fig.* 588.) the first (*m.* 1) is a little larger than the last (*m.* 3), which is the

Fig. 588.



Dental series, lower jaw, adult male, Troglodytes niger. (*Natural Size.*)

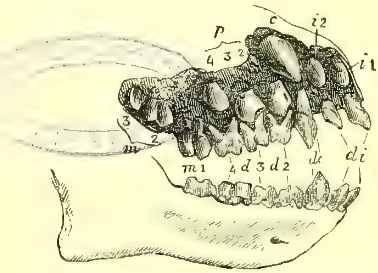
only molar in the smaller Chimpanzee as large as the corresponding tooth in the black varieties of the human subject *, in most of which, especially the Australians, the true molars attain larger dimensions than in the yellow or white races. The four principal cusps, especially the two inner ones, of the first molar of both species of Chimpanzee are more pointed and prolonged than in Man; a fifth small cusp is developed behind the outer pair, as in the Orangs and the Gibbons, but is less than that in Man. The same additional cusp is present in the second molar, which is seldom seen in Man. The crucial groove on the grinding surface is much less distinct than in Man, not being continued across the ridge connecting the anterior pair of cusps in the Chimpanzee. The crown of the third molar is longer antero-posteriorly from the greater development of the fifth posterior cusp, which, however, is rudimental in comparison with that in the Semnopitheques and Macaques. All the three true molars are supported by two distinct and well developed antero-posteriorly compressed divergent fangs, longitudinally excavated on the sides turned towards each other; in the white and yellow races of the human subject these fangs are usually connate in *m.* 3, and sometimes also in *m.* 2. The molar series in both species of Chimpanzee forms a straight line, with a slight tendency in the upper jaw to bend in the opposite direction to the well-marked curve which the same series describes in the human subject.

This difference of arrangement, with the more complex implantation of the premolars, the proportionally larger size of the incisors as compared with the molars; the still greater relative magnitude of the canines; and, above all, the sexual distinction in that respect, illustrated by *figs.* 585. 587., stamp the Chimpanzees most decisively with not merely specific but generic distinctive characters as compared with Man. For the teeth are fashioned in their shape and proportions in the dark recesses of their closed formative alveoli, and do not come into the sphere of operation of external modifying causes until the full size of the crowns has been acquired. The formidable natural weapons, with which the Creator has armed the powerful males of both species of Chimpanzee, form the compensation for the want of that psychical capacity to forge destructive instruments which has been reserved as the exclusive prerogative of Man. Both Chimpanzees and Orangs differ from the human subject in the order of the development of the permanent series of teeth; the second molar (*m.* 2) comes into place before either of the premolars has cut the gum, and the last molar (*m.* 3) is acquired before the canine. We may well suppose that the larger grinders are earlier required by the frugivorous Chimpanzees and Orangs than by the higher organised omnivorous species with more numerous and varied resources, and probably one main condition of the earlier development of the canines and premolars in Man may be their smaller relative size.

* See my Odontography, pl. 119, *fig.* 2, *m.*

In the South American Quadrumana, the number of teeth is increased to thirty-six (art. QUADRUMANA, Vol. IV. p. 210.; *Cebinæ* *), by an addition of one tooth to the molar series on each side of both jaws. It might be concluded, *à priori*, that as three is the typical number of true molars in the placental Mammalia with two sets of teeth, the additional tooth in the *Cebinæ* would be a premolar, and form one step to the resumption of the normal number (four) of that kind of teeth. The proof of the accuracy of this inference is given by the state of the dentition in the young *Cebus* in *fig.* 589., which corresponds with that of the human child in *fig.* 584., *i. e.* the whole of the deciduous dentition is retained, and the first true molar (*m.* 1) is in place on each side of both jaws. The germs of the other teeth of the permanent series are exposed in the upper jaw; and the crown of a premolar is found above the third molar in place, as well as above the second and first. As regards number, therefore, the molar series, in *Cebus*, is intermediate between that of *Mustela* (*fig.* 580., IV.) and *Felis* (ib. V.); the little premolar *p. i.* in *Mustela* tells plainly enough which of the four is wanting to complete the typical number in the South American Monkey, and which is the additional premolar distinguishing its dental formula from that of the Old World monkeys and man. By reference to Prof. Vrolik's article (QUADRUMANA) it will be seen that the eighth genus, including the little Marmoset monkeys (*Hapale*, *Ouistiti*), "have only the same number of teeth as the monkeys of the Old World, viz. 32, $i.\ \frac{4}{4}$, $c.\ \frac{1-1}{1-1}$, $m.\ \frac{5-5}{5-5}$." But the difference is much greater than this numerical conformity would intimate. In a young *Jacchus penicillatus* I find that there are three deciduous molars displaced by three premolars, as in the other South American Quadrumana, and that it is the last true molar, *m.* 3, the development of which is suppressed, not the premolar *p.* 2, and thus these diminutive squirrel-like monkeys actually differ

Fig. 589.



Deciduous and permanent teeth of Cebus.

* The dental series seems, unluckily, not to have been complete in either of the skulls represented by the distinguished author of that able article (*figs.* 132, 133).

from the Old World Quadrumana more than the *Cebidæ* do; *i.e.* they differ not only in having four teeth ($p.\ 2\ \frac{1-1}{1-1}$), which the monkeys of the Old World do not possess, but also by wanting four teeth ($m.\ 3\ \frac{1-1}{1-1}$), which those monkeys, as well as the *Cebidæ*, actually have. It is thus that the investigation of the exact homologies of parts leads to a recognition of the true characters indicative of zoological affinity.

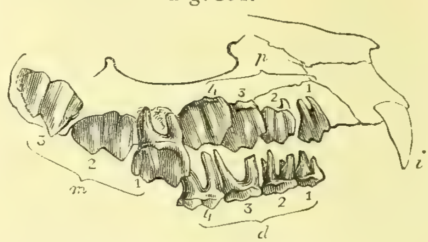
Most of the *Lemurinæ* have $p.\ \frac{3-3}{3-3}$, $m.\ \frac{3-3}{3-3}$, together with remarkable modifications of their incisive and canine teeth, of which an extreme example is shown in the pectinated tooth (*fig.* 556.) of the *Galeopithecus*. The inferior incisors slope forwards in all, and the canines also, which are contiguous to them, and very similar in shape. In the *Chirogaleus* these canines are entered as incisors in the dental formula of the genus (Vol. IV. p. 215), and the laniariform premolar (*p.* 2) is entered as a canine: M. Vrolik also describes four teeth on each side of the upper jaw, and four on each side of the lower jaw, as true tuberculated molars. They have tuberculated crowns, but the value of shape as a character is too small to permit our accepting so great an anomaly without the requisite proof of their order of development and succession.

Even in the hoofed quadrupeds with toes in uneven number (*Perissodactyla*), whose premolars, for the most part, repeat both the form and the complex structure of the true molars, such premolars are distinguished by the same character of development as those of the *Artiodactyla*, or Ungulates with toes in even number; although in these the premolars are distinguished also by modifications of size and shape. The complex ridged and tuberculate crowns of the second, third, and fourth grinders of the Rhinoceros, Hyrax (*fig.* 590.), and horse, no more prove them to be true molars, than the trenchant shape of the lower carnassials of the lion proves them to be false molars. It is by development alone that the primary division of the series of grinding teeth can be established, and by that character only can the homologies of each individual tooth be determined, and its proper symbol applied to it.

In pl. 136, *fig.* 5, of my Odontography, the three posterior teeth of the almost uniform grinding series of the horse's dentition are thus proved to be the only ones entitled to the name of "true molars;" and, if any one should doubt the certainty of the rule of counting, by which the symbols, *p.* 4, *p.* 3, and *p.* 2, are applied to the three large anterior grinding teeth (ib. *fig.* 19), which are commonly the only premolars present in each lateral series of the horse's jaws, yet the occasional retention of the diminutive tooth, *p.* 1 (ib. *fig.* 6), would establish its accuracy, whether such tooth be regarded as the first of the deciduous series unusually long retained, or the unusually small and speedily lost successor (*p.* 1) of an abortive *d* 1.

The law of development, so beautiful for its instructiveness and constancy in the placental *Diphyodonts*, is here illustrated in the little *Hyrax* (*fig.* 591.), in which the *d.* 1 is

Fig. 591.

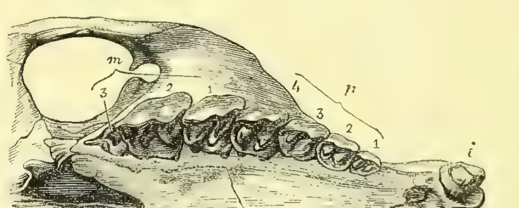


Deciduous and permanent molars of the Hyrax.

normally developed and succeeded by a permanent *p.* 1, differing from the rest only by a graduated inferiority of size, which, in regard to the last premolar, ceases to be a distinction between it and the first true molar.

The elephant, which by its digital characters belongs to the odd-toed, or perissodactyle, group of Pachyderms, also resembles them in the close agreement in form and structure of the grinding teeth representing the premolars, with those that answer to the true molars of the Hyrax, Tapir, and Rhinoceros. The gigantic Proboscidian Pachyderms of Asia and Africa present, however, so many peculiarities of structure, as to have led to their being located in a particular family in the Systematic Mammalogies. And this seems to be justified

Fig. 590.



Molar series, upper jaw (Hyrax).

by no character more than by the singular seeming exception which they present to the Diphyodont rule which governs the dentition of other hoofed quadrupeds. In fact, the elephant, like the Dugong, sheds and replaces vertically only its incisors, which are also two in number, very long, and of constant growth, forming tusks, with an analogous sexual difference in this respect in the female of the Asiatic species. The molars, also, are successively lost, are not vertically replaced, and are reduced finally to one on each side of both jaws, which is larger than any of its predecessors. These analogies are interesting and suggestive in connection with the other approximations in the "Sirenia" to the pachydermal type, which I have pointed out in the "Proceedings of the Zoological Society."*

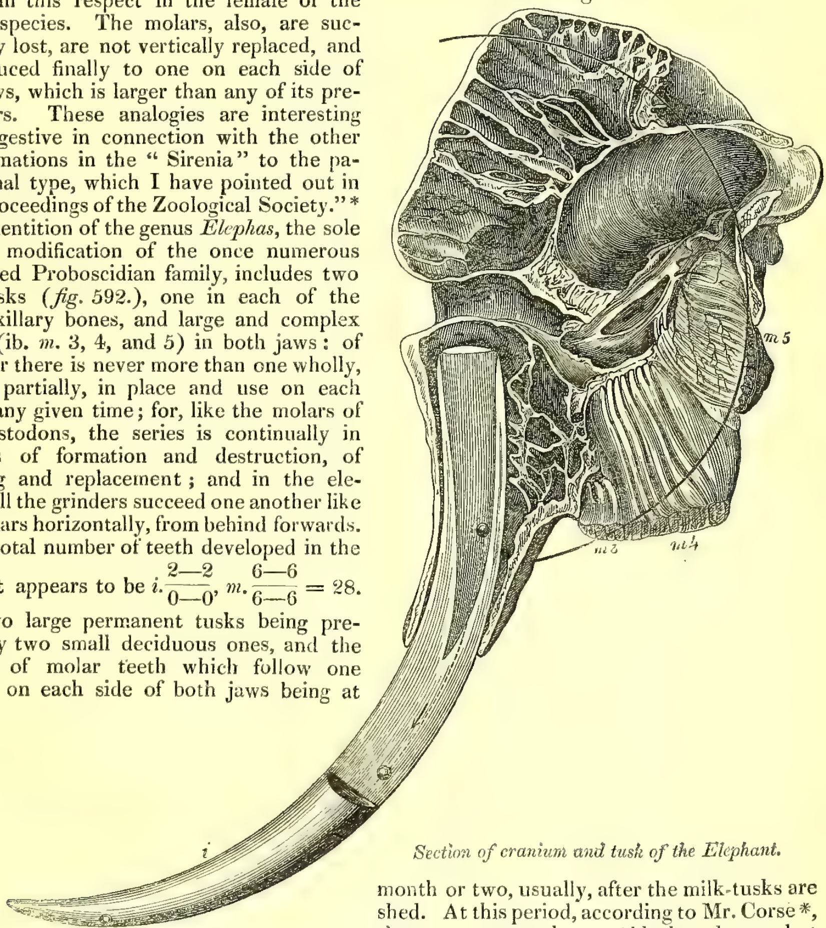
The dentition of the genus *Elephas*, the sole existing modification of the once numerous and varied Proboscidian family, includes two long tusks (*fig.* 592.), one in each of the Intermaxillary bones, and large and complex molars (ib. *m.* 3, 4, and 5) in both jaws: of the latter there is never more than one wholly, or two partially, in place and use on each side at any given time; for, like the molars of the Mastodons, the series is continually in progress of formation and destruction, of shedding and replacement; and in the elephants all the grinders succeed one another like true molars horizontally, from behind forwards.

The total number of teeth developed in the elephant appears to be $i.\frac{2-2}{0-0}, m.\frac{6-6}{6-6} = 28$. The two large permanent tusks being preceded by two small deciduous ones, and the number of molar teeth which follow one another on each side of both jaws being at least six, of which the last three may, by analogy, be regarded as answering to the true molars of other Pachyderms. I have shown in my Odontography that: —

"The deciduous tusk makes its appearance beyond the gum between the fifth and seventh month; it rarely exceeds two inches in length, and is about a third of an inch in diameter at its thickest part, where it protrudes from the socket; the fang is solidified, and contracts to its termination, which is commonly a little bent, and is considerably absorbed by the time the tooth is shed, which takes place between the first and second year.†

"The socket of the permanent tusk in a new-born elephant, is a round cell about three lines in diameter, situated on the inner and posterior side of the aperture of the temporary socket. The permanent tusks cut the gum when about an inch in length, a

Fig. 592.



Section of cranium and tusk of the Elephant.

month or two, usually, after the milk-tusks are shed. At this period, according to Mr. Corse*, the permanent tusks are 'black and ragged at the ends. When they become longer, and project beyond the lip, they soon are worn smooth by the motion and friction of the trunk.' Their widely open base is fixed upon a conical pulp, which, with the capsule surrounding the base of the tusk and the socket, continues to increase in size and depth, obliterating all vestiges of that of the deciduous tusk, and finally extending its base close to the nasal aperture (*fig.* 592.). The tusk is formed by successive calcification of layers of the pulp in contact with the inner surface of the pulp cavity; and, being subject to no habitual attrition from an opposed tooth, but being worn only by the occasional uses to which it is applied, it arrives at an extraordinary length, following the curve originally

* 1838, p. 40.

† See Mr. Corse's "Memoir on the Teeth of the Elephant," in Philosophical Transactions, 1799, p. 211: a good figure of the deciduous tusk is given in plate 5.

* Loc. cit., p. 212.

impressed upon it by the form of the socket, and gradually widening from the projecting apex to that part which was formed when the matrix and the socket had reached their full size.

"These incisive teeth of the elephant not only surpass other teeth in size, as belonging to a quadruped so enormous, but they are the largest of all teeth in proportion to the size of the body; representing in a natural state those monstrous incisors of the Rodents, which are the result of accidental suppression of the wearing force of the opposite teeth."

The tusks of the elephant, like those of the Mastodon, consist chiefly of that modification of dentine which is called "ivory," and which shows, on transverse fractures or sections, striæ proceeding in the arc of a circle from the centre to the circumference, in opposite directions, and forming by their decussations curvilinear lozenges. This character is peculiar to the Proboscidian Pachyderms.

In the Indian elephant the tusks are always short and straight in the female, and less deeply implanted than in the male: she thus retaining, as usual, more of the characters of the immature state. In the male they have been known to acquire a length of nine feet, with a basal diameter of eight inches, and to weigh one hundred and fifty pounds; but these dimensions are rare in the Asiatic species.

Mr. Corse, speaking of the variety of Indian elephant, called "Dauntelah" from its large tusks, which project almost horizontally with a slight curve upwards and outwards, says, "The largest I have known in Bengal did not exceed seventy-two pounds avoirdupois; at Tiperah they seldom exceed fifty pounds." There are varieties of the Dauntelah in which the large tusks of the male are nearly or quite straight; and in a more marked breed called "Mooknah," the tusks are much smaller, are straight, and point directly downwards. These ascertained varieties in an existing species ought to weigh with the observers of analogous varieties in the teeth of fossil Proboscidians, before they pronounce definitely on their value as characters of distinct species. More anomalous varieties occasionally present themselves in the Indian Elephant, as when one tusk is horizontal, the other vertical; or when, from some distortion of the alveolus, a spiral direction is impressed upon the growth of the tusk, as in that specimen figured by Grew in the "Rarities of Gresham College," Tab. 4., and which is now in the Museum of the Royal College of Surgeons, London. The tusk of the elephant is slightly moveable in its socket, and readily receives a new direction of growth from habitual pressure; this often causes distorted tusks in captive elephants, and Cuvier * relates the mode in which advantage was taken of the same impressibility, in order to rectify the growth of such tusks in an elephant kept at the Garden of Plants.

The tusks of the extinct *Elephas primigenius*, or Mammoth, have a bolder and more extensive curvature than those of the *Elephas indicus:* some have been found which describe a circle; but, the curve being oblique, they thus clear the head, and point outwards, downwards, and backwards. The numerous fossil tusks of the Mammoth which have been discovered and recorded, may be ranged under two averages of size: the larger ones at nine feet and a half, the smaller at five feet and a half in length. I have elsewhere * assigned reasons for the probability of the latter belonging to the female Mammoth, which must accordingly have differed from the existing elephant of India, and more resembles that of Africa in the development of her tusks; yet manifesting an intermediate character by their smaller size. Of the tusks which are referable to the male Mammoth, one from the newer tertiary deposits in Essex, measured nine feet ten inches along the outer curve, and two feet five inches in circumference at its thickest part; another from Eschscholtz Bay was nine feet two inches in length, and two feet one and a half inches in circumference, and weighed one hundred and sixty pounds. A Mammoth's tusk has been dredged up off Dungeness which measured eleven feet in length. In several of the instances of Mammoth's tusks from British strata, the ivory has been so little altered as to be fit for the purposes of manufacture; and the tusks of the Mammoth, which are still better preserved in the frozen drift of Siberia, have long been collected in great numbers as articles of commerce.†

Cuvier ‡ states that the elephant of Africa, at least in certain localities, has large tusks in both sexes, and that the female of this species, which lived seventeen years in the menagerie of Louis XIV., had larger tusks than those in any Indian elephant, male or female, of the same size which he had seen. The ivory of the tusks of the African elephant is most esteemed by the manufacturer for its density and whiteness.

The molar teeth of the elephant are remarkable for their great size, even in relation to the bulk of the animal, and for the extreme complexity of their structure. The crown, of which a great proportion is buried in the socket, and very little more than the grinding surface appears above the gum, is deeply divided into a number of transverse perpendicular plates (*fig.* 557), consisting each of a body of dentine (*d*), coated by a layer of enamel (*e*), and this again by the less dense bone-like

* Ossemens Fossiles, 4to. 1821, tom. i. p. 47.

† In the account of the Mammoth's bones and teeth of Siberia, published in the "Philosophical Transactions" for 1737 (No. 446), tusks are cited which weighed two hundred pounds each, and "are used as ivory, to make combs, boxes, and such other things; being but little more brittle, and easily turning yellow by weather and heat." From that time to the present there has been no intermission in the supply of ivory, furnished by the tusks of the extinct elephants of a former world.

‡ Loc. cit., p. 55.

substance (c) which fills the interspaces of the enamelled plates, and here more especially merits the name of "cement," since it binds together the several divisions of the crown before they are fully formed and united by the confluence of their bases into a common body of dentine. As the calcification of each plate begins at the summit, they remain detached from each other and like so many separate teeth or denticules, until their base is completed, when it becomes blended with the bases of contiguous plates to form the common body of the crown of the complex tooth from which the roots are next developed.

The plates of the molar teeth of the Siberian Mammoth (*Elephas primigenius*) are thinner in proportion to their breadth, and are generally a little expanded at the middle; and they are more numerous in proportion to the size of the crown than in the existing species of Asiatic Elephant. In the African Elephant, on the other hand, the lamellar divisions of the crown are fewer and thicker, and they expand more uniformly from the margins to the centre, yielding a lozenge-form when cut or worn transversely, as in mastication.

The horizontal as well as vertical course of development of the elephant's grinder is well illustrated by the Mammoth's molar, the last of the lower jaw. The separate digital processes of the posterior plates are still distinct, and adhere only by the remaining cement; a little in advance we see them united to form the transverse plate; and, at the opposite extremity of the tooth, the common base of dentine is exposed by which the plates are finally blended into one individual complex grinder*; this never takes place simultaneously along the whole course of the tooth in the larger molars of the existing Indian elephant, or its extinct congener, the Mammoth. The African elephant, and some of the extinct Indian species, as the *El. planifrons*, manifest their affinity to the Mastodon by the basal confluence of the hindmost plates before the foremost ones are worn out. The formation of each grinder begins with the summits of the anterior plate, and the rest are completed in succession; the tooth is gradually advanced in position as its growth proceeds; and, in the existing Indian elephant, the anterior plates are brought into use before the posterior ones are formed. When the complex molar cuts the gum the cement is first rubbed off the digital summits: then their enamel cap is worn away, and the central dentine comes into play with a prominent enamel ring; the digital processes are next ground down to their common uniting base, and a transverse tract of dentine with its wavy border of enamel is exposed; finally, the transverse plates themselves are abraded to their common base of dentine, and a smooth and polished tract of that substance is produced.* From this basis the roots of the molar are developed, and increase in length to keep the worn crown on the grinding level, until the reproductive force is exhausted. When the whole extent of a grinder has successively come into play, its last part is reduced to a long fang supporting a smooth and polished field of dentine, with, perhaps, a few remnants of the bottom of the enamel folds at its hinder part. When the complex molar has been thus worn down to a uniform surface it becomes useless as an instrument for grinding the coarse vegetable substances on which the elephant subsists; it is attacked by the absorbent action, and the wasted portion of the molar is finally shed.

The grinding teeth of the elephant progressively increase in size, and in the number of lamellar divisions, from the first to the last; and, as the rate of increase in both respects is nearly identical in both jaws, I shall describe them chiefly as they appear in the lower one.

The *first molar*, which cuts the gum in the course of the second week after birth, has a sub-compressed crown, nine lines in antero-posterior diameter, divided by three transverse clefts into four plates, the third being the broadest, and the tooth here measuring six lines across †; the first and second plates have two mammilloid summits; the third and fourth have three or four such; there is a single and sometimes a double mammilloid summit at the fore and back part of the crown: the base slightly contracts, and forms a neck as long as the enamelled crown, but of less breadth, and this divides into two, an anterior and posterior, long, sub-cylindrical, diverging, but mutually incurved fangs; the total length of this tooth is one inch and a half. The corresponding upper molar, which Mr. Corse describes as cutting the gum a little earlier than the lower one, has the anterior single digital process or mammilla, and the posterior talon developed into a fifth plate, smaller than the fourth, with which its middle part is confluent; the neck of this tooth is shorter, and the two fangs are shorter, larger, and more compressed than those of the lower first molar. This tooth is the homologue of the probably deciduous molar (d. 2) in other

* Some anatomists describe the divisions of the crown of the elephant's grinder as so many "distinct teeth;" and Mr. Corse (loc. cit. p. 213.), who first propounded this view, calls each complex grinder "a case of teeth," and states "that these teeth are merely joined to each other by an intermediate softer substance, acting like a cement." But this description applies only to the imperfectly-formed tooth; and the detached eminences of the crown of any complex tooth, at that stage of growth when they are held together only by the still uncalcified supporting matrix, might with equal justice be regarded as so many distinct teeth.

* In the fossil specimen figured in plate 147, of my "Odontography," the left molar l, exhibits all the above-described gradations of use; but the right molar, r, through some accident to the opposing tooth in the lower jaw, has not been so worn, but projects beyond the level of the left molar, with the mammillated margins of the plates entire.

† These are also the dimensions of the first lower molar figured by Mr. Corse, loc. cit. pl. vi. *fig.* 1, D, and *fig.* 3; but I have seen the first lower molar of smaller dimensions.

Ungulates; it is not a mere miniature of the great molars of the mature animal, but retains, agreeably with the period of life at which it is developed, a character much more nearly approaching that of the ordinary Pachydermal molar, manifesting the adherence to the more general type by the minor complexity of the crown, and by the form and relative size of the fangs. In the transverse divisions of the crown we perceive the affinity to the Tapiroid type, the different links connecting which with the typical elephants are supplied by the extinct Lophiodons, Dinotheriums, and Mastodons. The sub-division of the summits of the primary plates recalls the character of the molars, especially the smaller ones, of the Phacochere in the Hog-tribe. As the elephant advances in age the molars rapidly acquire their more special and complex character.

The first molars are completely in place, and in full use at three months, and are shed when the elephant is about two years old.

The sudden increase and rapid development of the *second molar* may account for the non-existence of any vertical successor to the former tooth, or "premolar," in the elephant. The eight or nine plates of the crown are formed in the closed alveolus, behind the first molar by the time this cuts the gum, and they are united with the body of the tooth, and most of them in use, when the first molar is shed.

The average length of the second molar is two inches and a half; ranging from two inches to two inches and nine lines. The greatest breadth, which is behind the middle of the tooth, is from one inch to one inch three lines. There are two roots: the cavity of the small anterior one expands in the crown, and is continued into that of the three anterior plates. The thicker root supports the rest of the tooth. The second molar is worn out and shed before the beginning of the sixth year.

The *third molar* has the crown divided into from eleven to thirteen plates; it averages four inches in length, and two inches in breadth, and has a small anterior, and a very large posterior root; it begins to appear above the gum about the end of the second year, is in its most complete state and extensive use during the fifth year, and is worn out and shed in the ninth year. The last remnant of the third molar is shown at *m.* 3, *fig.* 592.

It is probable that the three teeth above described are homologous with the deciduous molars, *d.* 2, *d.* 3, and *d.* 4, in the Hyrax and horse.

The *fourth molar* presents a marked superiority of size over the third, and a somewhat different form: the anterior angle is more obliquely abraded, giving a pentagonal figure to the tooth in the upper jaw (*fig.* 592. *m.* 4). The number of plates in the crown of this tooth is fifteen or sixteen: its length between seven and eight inches; its breadth three inches. It has an anterior simple and slender root supporting the three first plates; a second of larger size and bifid, supporting the four next plates; and a large contracting base for the remainder. The fore-part of the grinding surface of this tooth begins to protrude through the gum at the sixth year: the tooth is worn away, and its last remnant shed, about the twentieth or twenty-fifth year. It may be regarded as the homologue of the first true molar of ordinary Pachyderms (*m.* 1).

The *fifth molar*, with a crown of from seventeen to twenty plates, measures between nine and ten inches in length, and about three inches and a half in breadth. The second root is more distinctly separated from the first simple root than from the large mass behind. It begins to appear above the gum about the twentieth year: its duration has not been ascertained by observation; but it probably is not shed before the sixtieth year.

The *sixth molar* appears to be the last, and has from twenty-two to twenty-seven plates; its length, or antero-posterior extent, following the curvature, is from twelve to fifteen inches: the breadth of the grinding surface rarely exceeds three inches and a half.

The reproductive power of the matrix in some cases surpasses that of the formative development of the cavity for lodging the tooth, and the last lamellæ are obliged to be folded from behind forwards upon the side of the tooth. *Fig.* 99, p. 233. of my "History of British Fossil Mammals," shows this condition in the last lower molar of the Mammoth.

One may reasonably conjecture that the sixth molar of the Indian elephant, if it make its appearance about the fiftieth year, would, from its superior depth and length, continue to do the work of mastication until the ponderous Pachyderm had passed the century of its existence.

Mr. Corse has figured the sixth molar, (which he calls the seventh or eighth,) with twenty-three plates, in tab. x. of his Memoir, and a small cavity, c, is marked as an incipient alveolus for a succeeding grinder. Had it actually been such, it might have been expected to contain some calcified portions of the anterior plates of such succeeding grinder.

The molar teeth, in all the species of elephant, succeed each other from behind forwards, moving, not in a right line, but in the arc of a circle, shown by the curved line in *fig.* 592. The position of the growing tooth in the closed alveolus (*m.* 5) is almost at right angles with that in use, the grinding surface being at first directed backwards in the upper jaw, and forwards in the lower jaw, and brought, by the revolving course, into a horizontal line in both jaws, so that they oppose each other, when developed for use. The imaginary pivot on which the grinders revolve is next their root in the upper jaw, and is next the grinding surface in the lower jaw; in both, towards the frontal surface of the skull. Viewing both upper and lower molars as one complex whole, subject to the same revolving movement, the section dividing such whole into upper and lower portion runs parallel to the curve described by that movement, the upper being the central portion, or that nearest the pivot, the lower, the peripheral portion: the grinding surface of the upper molars is consequently convex from behind forwards, and that of the lower molars concave: the upper molars are always broader than the lower ones. The bony plate forming the sockets of the growing teeth is more than usually distinct from the body of the maxillary, and participates in this revolving course, advancing forwards with the teeth. The partition between the tooth in use and its successor is perforated near the middle; and, in its progress forwards, that part next the grinding surface is first absorbed; the rest disappearing with the absorption of the roots of the preceding grinder.

There are few examples of organs that manifest a more striking adaptation of a highly complex and beautiful structure to the exigencies of the animal endowed with it, than the grinding teeth of the elephant. We perceive, for example, that the jaw is not encumbered with the whole weight of the massive tooth at once, but that it is formed by degrees as it is required; the division of the crown into a number of successive plates, and the subdivision of these into cylindrical processes, presenting the conditions most favourable to progressive formation. But a more important advantage is gained by this subdivision of the tooth; each part is formed like a perfect simple tooth, having a body of dentine, a coat of enamel, and an outer investment of cement: a single digital process may be compared to the simple canine of a Carnivore; a transverse row of these, therefore, when the work of mastication has commenced, presents, by virtue of the different densities of their constituent substances, a series of cylindrical ridges of enamel, with as many depressions of dentine, and deeper external valleys of cement: the more advanced and more abraded part of the crown is traversed by the transverse ridges of the enamel inclosing the depressed surface of the dentine, and separated by the deeper channels of the cement: the fore-part of the tooth exhibits its least efficient condition for mastication; the inequalities of the grinding surface being reduced in proportion as the enamel and cement which invested the dentinal plates have been worn away. This part of the tooth is, however, still fitted for the first coarse crushing of the branches of a tree: the transverse enamel ridges of the succeeding part of the tooth divide it into smaller fragments, and the posterior islands and tubercles of enamel pound it to the pulp fit for deglutition. The structure and progressive development of the tooth not only give to the elephant's grinder the advantage of the uneven surface which adapts the millstone for its office, but, at the same time, secure the constant presence of the most efficient arrangement for the finer comminution of the food, at the part of the mouth which is nearest the fauces.

With regard to the *microscopic structure* of the peculiar modification of dentine called "ivory," this is characterised partly by the minute size of the tubes, which, at their origin from the pulp cavity, do not exceed $\frac{1}{15000}$th of an inch in diameter, in their close arrangement at intervals scarcely exceeding the breadth of a single tube, and, above all, on their strong and almost angular gyrations, which are much greater than the secondary curvatures of the tubes of ordinary dentine.

The dentinal tubes of ivory, as they radiate from the pulp-cavity, incline obliquely towards the pointed end of the tusk, and describe two slight primary curves, the first convex towards that end, the second and shorter one concave; these curves in narrow sections from near the open base of the tusk are almost obscured by the strong angular parallel secondary gyrations. The tubes divide dichotomously, at acute angles, and gradually decrease in size as they approach the periphery of the tusk.

The characteristic appearance of decussating curved striæ, with oblique rhomboidal spaces, so conspicuous on transverse sections or fractures of ivory, is due to the refraction of light caused by the parallel secondary gyrations of the tubes above described. The strong contour lines observed in longitudinal sections of ivory, parallel with the cone of the pulp-cavity, and which are circular and concentric when viewed in transverse slices of the tusk, are commonly caused by strata of minute opaque cellules, which are unusually numerous in the interspaces of the tubes throughout the substance of the ivory, and by their very great abundance and larger size in the peripheral layers of cement. The close-set lateral branches of the calcigerous tubes unite with the tubuli of the cells. The decomposition of the fossil tusks into superimposed conical layers takes place along the strata of the opaque cellules, and directly across the course of the calcigerous gyrating tubes.

The radiated cells of the true cement are larger and more uniform in size and shape; many of them approach nearer the circular figure than in ordinary teeth; the long axis of the more elliptical ones is parallel with the plane of the stratum of cement; their average diameter is $\frac{1}{2500}$th of an inch, and their interspaces sometimes do not exceed that dimension. The cemental tubuli appear from their course, and sometimes from the overlapping of the substances in the sections examined, to be directly continued from the tubuli of the ivory; but Retzius expressly denies the continuation, and states that the cemental tubes at both the outer and the inner surface of the cement have terminations of less diameter than their middle part. This is exact with respect to the major part of the cement. In that near the base of the tusk I have seen a few vascular canals. The contour lines of the cement are usually wavy, and not parallel with the line of the outer surface of the ivory.

In the tusks of the *Mastodon giganteus* the outer layer of cement is relatively thicker than in the tusks of the Mammoth or in those of the Indian elephant. The general character of the microscopic structure of the ivory of the Mastodon's tusk is the same as that of the elephant. The peripheral extremities of the dentinal tubes are, in some parts of the tusk, straighter than in the rest of their course; the straighter extremities were those which were first formed in the calcification of the peripheral part of the pulp, and this first-formed ivory is accordingly, in such parts, more like the ordinary dentine, and is analogous to the thin peripheral cap of such substance in the teeth of the Sloth and of some fishes.

The pulp soon, however, becomes subject to that modification of the calcifying processes by which the more tortuous disposition of the tubuli and the more frequent interposition of opaque cellules are produced; modifications which, in establishing the characters of ivory, present a step in the transition from true dentine to osteo-dentine.

By the minuteness and close arrangement of the tubes, and especially by their strongly undulating secondary curves, a tougher and more elastic tissue is produced than results from their disposition in ordinary dentine; and the modification which distinguishes "ivory" is doubtless essential to the due degree of coherence of so large a mass as the elephant's tusk, projecting so far from the supporting socket, and to be frequently applied in dealing hard blows and thrusts.

The central part of the tusk, especially near the base of such as have reached their full size, is occupied by a slender cylindrical tract of modified ivory, perforated by a few vascular canals, which is continued to the apex of the tusk. It is not uncommon to find processes of osteo-dentine or imperfect bone-like ivory, projecting in a stalactitic form * into the interior of the pulp-cavity, apparently the consequence of partial inflammation or malformation of the vascular pulp. The musket-balls and other foreign bodies which are occasionally found in ivory, are immediately surrounded by osteo-dentine in greater or less quantity. It has long ceased to be a matter of wonder how such bodies should become completely imbedded in the substance of the tusk, sometimes without any visible aperture, or how a leaden bullet may have become lodged in the solid centre of a very large tusk without having been flattened. Such a ball, aimed at the head of an elephant, may penetrate the thin bony socket and the thinner ivory parietes of the wide conical pulp-cavity occupying the inserted base of the tusk; if the projectile force was there spent, the ball would gravitate to the opposite and lower side of the pulp-cavity, as indicated in *fig.* 592.† The presence of the foreign body exciting inflammation of the pulp, an irregular course of calcification ensues, which results in the disposition around the ball of a certain thickness of osteo-dentine. The pulp then resuming its healthy state and functions, coats the inner surface of the osteo-dentine inclosing the ball, together with the rest of the conical cavity into which that mass projects, with layers of normal ivory.*

The portion of the cement-forming capsule surrounding the base of the tusk, and the part of the pulp, which were perforated by the ball in its passage, are soon replaced by the active reparative power of these highly vascular bodies. The hole formed by the ball in the base of the tusk is then more or less completely filled up by a thick coat of cement from without and of osteo-dentine from within. Traces of such a cicatrix closing the entrance have been more than once noticed: and Blumenbach deduced, therefrom, a property in the elephant's tusk to pour out bony matter in order to heal such wounds. The reparation is however effected by the calcification of the reproduced parts of the capsule and pulp.

By the continued progress of growth, the ball so inclosed is carried forwards, in the course indicated by the arrow in *fig.* 592., to the middle of the solidified exserted part of the tusk, as in the example in Blumenbach's collection which he considered so curious. Should the ball have penetrated the base of the tusk of a young elephant, it may be carried forwards by the uninterrupted growth of the tusk until that base has become the apex, and be finally exposed and discharged by the continual abrasion to which the apex of the tusk is subjected. Yet none of these phenomena prove the absolute non-vascularity of the tusk, but only the low degree of its vascularity. Blood circulates, slowly no doubt, through the minute vascular canals which are continued through the centre of the ivory to the very apex of the tusk: and it is from this source that the fine tubular structure of the ivory obtains the plasmatic colourless fluid by which its low vitality is maintained.

Development.—The matrix of the tusk consists of a large conical pulp, which is renewed quicker than it is converted, and thus is not only preserved, but grows, up to a certain period of the animal's life: it is lodged in the cavity at the base of the tusk; this base is surrounded by the remains of the capsule, a soft vascular membrane of moderate thickness, which is confluent with the border of the base of the pulp, where it receives its principal vessels.

* Haller seems to have been the first to notice these irregular internal deposits in the pulp-cavity of the elephant's tusk. Elementa Physiologiæ, tom. viii. p. 519.

† Camper, "Description Anatomique d'un Eléphant Male," fol. p. 54. Cuvier, Annales du Muséum, tom. viii. (1806) p. 115.

* Cuvier, "Annales du Muséum," tom. viii. p. 115, 1806, "Sur les défenses des éléphans, la structure, l'accroissement, les caractères distinctifs de l'ivoire, et sur les maladies," first clearly stated that the ball or foreign body in the tusk of the elephant was immediately surrounded by a substance different from the regular ivory. The great anatomist observes, "Toute la portion d'ivoire en dehors de la balle est semblable au reste; il n'y a que ce qui l'entoure immédiatement qui soit irrégulier."

I had the tusk and pulp of the great elephant at the Zoological Gardens longitudinally divided, soon after the death of that animal in the summer of 1847. Although the pulp could be easily detached from the inner surface of the pulp-cavity, it was not without a certain resistance, and when the edges of the co-adapted pulp and tooth were examined by a strong lens, the filamentary processes from the outer surface of the pulp could be seen stretching, as they were withdrawn from the dentinal tubes, before they broke. They are so minute that, to the naked eye, the detached surface of the pulp seems to be entire, and Cuvier was thus deceived in concluding that there was no organic connection between the pulp and the ivory.* As the learned professor who has contributed the article "PACHYDERMATA" adopts Cuvier's description of the formation of the teeth of the elephant by deposition and transudation of the tissues from free surfaces of the formative organs, I have the more valued the rare opportunity of testing and confirming, by examination of the recent animal, the account of the processes of conversion of those organs into the dental tissues, which I gave in my "Odontography."

Each molar of the elephant is formed in the interior of a membranous sac—the capsule, the form of which partakes of that of the future tooth, being cubical in the first molar, oblong in the last, and rhomboidal in most of the intermediate teeth; but always decreasing in vertical extent towards its posterior end, and closed at all points, save where it is penetrated by vessels and nerves. It is lodged in an osseous cavity of the same form as itself, and usually in part suspended freely in the maxillary bone; the bony case being destined to form part of the socket of the tooth. The exterior of the membranous capsule is simple and vascular, as shown at *m*. 5, *fig*. 592.; its internal surface gives attachment to numerous folds or processes, as in most other Ungulate animals.

The dentinal pulp rises from the bottom of the capsule, or that part which lines the deepest part of the alveolus, in the form of transverse parallel plates extending towards that part of the capsule ready to escape from the socket. These plates adhere only to the bottom of the capsule; their opposite extremity is free from all adhesion. This summit is thinner than the base; it might be termed the edge of the plate: but it is notched, or divided into many digital processes. The tissue of these digitated plates is identical with that of the dentinal pulp of simple Mammalian teeth; it becomes also highly vascular at the parts where the formation of the dentine is in active progress.

Processes of the capsule descend from its summit into the interspaces of the dentinal pulp-plates, and consequently resemble them in form; but they adhere not only by their base to the surface of the capsule next the mouth, but also by their lateral margins to the sides of the capsule, and thus resemble partition-walls, confining each plate of the dentinal pulp to its proper chamber; the margin of the partition opposite its attached base is free in the interspace of the origins of the dentinal pulp plates. The enamel organ, which Cuvier appears to have recognised under the name of the internal layer of the capsule, is distinguishable by its light blue sub-transparent colour and usual microscopic texture, adhering to the free surface of the partitions formed by the true inner layer of the capsule. Although the enamel-pulp be in close contact with the dentinal pulp prior to the commencement of the formation of the tooth, one may readily conceive a vacuity between them, which is continued uninterruptedly, in many foldings, between all the gelatinous plates of the dentinal pulp, and the partitions formed by the combined enamel-pulp and the folds of the capsule. According to the excretion-view, this delicate apparatus must have been immediately subjected to the violence of being compressed in the unyielding bony box, by the deposition of the dense matters of the tooth in the hypothetical vacuity between the enamel and dentinal pulps; a process of absorption must have been conceived to be set on foot immediately that the altered condition of the gelatinous secreting organs took place; and, according to Cuvier's hypothesis, the secreting function must be supposed to have proceeded, without any irregularity or interruption, while the process of absorption was superinduced in the same part to relieve it from the effects of pressure produced by its own secretion.

The formation of the dentine commences immediately beneath the *membrana propria* of the pulp: a part which Cuvier distinctly recognised, and which he accurately traced as preserving its relative situation between the dentine and enamel throughout the whole formation of the dentine, and discernible in the completed tooth "as a very fine greyish line, which separates the enamel from the internal substance" or dentine.

The calcification and conversion of the cells of the dentinal pulp commence as usual at the peripheral parts of the lamelliform processes furthest from the attached base. It may readily be conceived, therefore, that, at the commencement, there is formed a little cap upon each of the processes into which the edges of the pulp-plates are divided. As the centripetal calcification proceeds the caps are converted into horn-shaped cones; when it has reached the bottom of the notches of the edge of the pulp-plate all the cones become united together into a single transverse plate; and, the process of conversion having reached the base of the pulp-plate, these plates coalesce to form a common base to the crown of the tooth, which would then present the same eminences and notches that characterised the gelatinous pulp, if, during the period of conversion, other substances had

* Annales du Muséum, tom. viii. (1806), p. 94. The account is repeated verbatim in the posthumous edition of the "Ossemens Fossiles," 1836.

not been formed upon the surface and in the interspaces of the pulp-plates.

Coincident, however, with the formation of the dentine, is the deposition of the hardening salts of the enamel in the extremely slender prismatic cells, which are for the most part vertical to the plane of the inner surface of the folds of the capsule to which they are attached; these cells or moulds give a subtransparent bluish tint to the enamel pulp. The true inner part of the capsule forms those thick transverse folds or partitions which support the enamel organ, and with it fill the interspaces of the dentinal pulps. With regard to the formation of the cement, Cuvier, after citing the opinion of Tenon — that it was the result of ossification of the internal layer of the capsule, and that of Blake — that it was a deposition from the opposite surface of the capsule to that which had deposited the enamel, states his own conviction to be that the cement is produced by the same layer and by the same surface as that which has produced the enamel. The proof alleged is, that so long as any space remains between the cement and the external capsule, that space is found to contain a soft internal layer of the capsule with a free surface next the cement. The phenomena could not, in fact, be otherwise explained according to the "excretion theory" of dental development. To the obvious objection that the same part is made, in this explanation, to secrete two different products, Cuvier replies, that it undergoes a change of tissue: "Whilst it yielded enamel only it was thin and transparent; to give cement it becomes thick, spongy, and of a reddish colour." * The external characters of the enamel organ and cement-forming capsule are correctly defined; only, the one, instead of being converted into the other, is in fact changed into its supposed transudation: the enamel fibres being formed, and properly disposed in the direction in which their chief strength is to lie, by the assimilative properties of the pre-arranged elongated prismatic non-nucleated cells, which take from the surrounding plasma the required salts and compact them in their interior.

Whilst this process is on foot, and before the enamel fibres are firm in their position, the capsule begins to undergo that change which results in the formation of the thick cement; the calcifying process commences from several points, and proceeds centrifugally, radiating therefrom, and differing from the ossification of bone chiefly in the number of these centres, which, though close to the new-formed enamel, are in the substance of the inner vascular surface of the capsular folds. The cells arrange themselves in concentric layers around the vessels, and act like those of the enamel pulp in receiving into their interior the bone-salts in a clear and compact state; during this process they become confluent with each other, their primitive distinctness being indicated only by their persistent granular nuclei, which now form the radiated Purkinjian corpuscles. The interspaces of the concentric series of confluent cells become filled with the calcareous salts in a rather more opaque state, and the conversion of the capsule into cement goes on, according to the processes more particularly described in the Introduction to my "Odontography," until a continuous stratum is formed in close connection with the layer of enamel.

The uncalcified part of the capsule, always much softer than cartilage, is very readily detached from the calcified part, and to the naked eye the separated surface seems entire, and might readily pass, as with Cuvier, for a secreting surface. But the fine vascular processes which have been torn from the medullary canals of the calcified part are conspicuous, and resemble villi, when the detached surface is examined, even with a moderate magnifying power, under water.

Calcification extending from the numerous centres, the different portions coalesce and progressively add to the thickness of the cement until all the interspaces of the coronal plates and the whole exterior of the crown is covered with the bone-like substance. The enamel-pulp ceases to be developed at the base of the crown, but the capsule continues to be formed *pari passu* with the partial formation of the pulp, as this continues, progressively contracting, from the base of the crown, to form by its calcification the roots. The calcification of the capsule going on at the same time, a layer of cement is formed in immediate connection with the dentine. The circumscribed spaces at the bottom of the socket to which the capsule and dentinal pulp adhere, where they receive their vessels and nerves, and which are the seat of the progressive formation of these respective moulds of the two dental tissues, become gradually contracted, and subdivided by the further localisation of the reproductive forces to particular spots, whence the subdivision of the base into roots. The surrounding bone undergoes corresponding modifications, growing and filling up the interspaces left by the dividing and contracting points of attachment of the residuary matrix. All is subordinated to one harmonious law of growth by vascular action and cell-formation, and of molecular decrement modifying form by absorption. Mechanical squeezing or drawing out have no share in these changes of the pulp or capsule; pressure at most exercises only a gentle stimulus to the vital processes. Cuvier believed that there were places where the dentinal pulp and the capsule were separate from each other. I have never found such except where the enamel-pulp was interposed between them in the crown of the tooth, or where both pulp and capsule adhered to the periosteum of the socket, below the crown.

* "Seulement elle change de tissue: tant qu'elle ne donnait que de l'émail, elle était mince et transparente; pour donner du cortical elle devient épaisse, spongieuse, opaque et rougeâtre." — Annales du Muséum, tom. viii. p. 99; Ossemens Fossiles, ed. 1834, 8vo. tom. i p. 514. Art. PACHYDERMATA, p. 869.

Cuvier affirms that the number of fangs of an elephant's molar depends upon the number of points at which the base of the gelatinous (dentinal) pulp is attached to the bottom of the capsule; and that the interspaces of these attachments constitute the under part of the crown or body of the tooth, the attachments themselves forming the first beginnings of the fangs. True to his hypothesis of the formation of the dental tissues by excretion, he says * that the elongation of the fangs is produced by two circumstances: first, the progressive elongation of the layers of osseous substance (dentine) which force the tooth to rise and emerge from its socket; secondly, the thickening of the body of the tooth by the addition of successive layers to its inner surface, which, filling up the interior cavity, leaves scarcely room for the gelatinous pulp, and forces it down into the interior of the roots.

This pulling up of the fang on the one hand, and squeezing down the pulp on the other, are forces too gross and mechanical to be admitted in actual physiology to explain the growth of the root of a tooth or of any other organised product; such modes of explanation were, however, inevitable in adopting the excretion theory of dental development.

With regard to the homologies of the complex molars of the Proboscidian quadrupeds, a species of insight which may come to be deemed, in the course of anatomical science, as of equal import to the knowledge of the formative processes of parts, I must admit that the mere fact of the marked and disproportionate increase of size of the first of the three last molars over its predecessor — the last of the first three that are developed — may appear but a feeble support to the analogical evidence on which, chiefly, I have classed the three last developed molars of the elephant, in a category distinct from that of their smaller predecessors. But the value of such indication and analogy will begin to be apparent when we examine the condition of dental development in the primeval forms of Proboscidians. I have already shown that the typical character of the Diphyodont dentition was more closely and generally adhered to in the genera that existed during the oldest tertiary periods in geology than in their actual successors: it became of course highly interesting to inquire whether the miocene Mastodons, the earliest of the great Proboscidian quadrupeds of which we have any cognizance, manifested any analogous closer adhesion to type than their elephantine successors, and whether they would afford any actual proof of the true deciduous nature of the first, second, or third molars, by the development of a vertical successor or premolar. Cuvier first ascertained the fact, though without appreciating its full significance, in a specimen of the upper jaw of the *Mastodon angustidens* from Dax, in which the second six-lobed deciduous molar was displaced by a four-lobed or quadricuspid premolar developed above it and succeeding it vertically.* The same important fact was subsequently confirmed by Dr. Kaup in observations of the *Mastodon longirostris* of the miocene tertiary deposits of Eppelsheim.†

This satisfactorily proves the true deciduous character of the first and second molars; and that the third molar in order of appearance ‡, is also one (the last) of the deciduous series, is indicated by the contrasted superiority of size of the ante-penultimate tooth, which I regard as the first of the true molar series.

The great extent and activity of the processes of dental development required for the preparation of the large and complex true molar teeth would seem to exhaust the power, which, in ordinary Pachyderms, is expended in developing the vertical successors of the deciduous teeth. In the primeval Mastodons above cited, this normal exercise of the reproductive force was not, however, wholly exhausted, and one premolar, of more simple form than its deciduous predecessor, was developed on each side of both jaws. But even this trace of adherence to the archetypal dentition is lost in the more modified Proboscidians of the present day.

Another and very interesting mark of adhesion to the archetype is shown by the development of two incisors in the lower jaw in the young of some of the Mastodons, by the retention and development of one of these inferior tusks in the male of the *Mastodon giganteus* of North America, and by the retention of both in the European *Mastodon longirostris*. No trace of these inferior homotypes of the great premaxillary tusks have been detected in the fœtus or young of the existing elephants.

In the gigantic *Dinotherium* the upper incisors were suppressed, and the two lower incisors were developed into huge tusks, which curved down from the symphysis of the massive under jaw. Most of the grinders had two transverse ridges on the crown, as in the Tapir; two deciduous molars, if not three, were succeeded vertically by two premolars, the second of which (*p*. 4 of the typical series) closely resembles the true molars, as in other Perissodactyles.

The typical dentition is departed from in the existing Hippopotamus by the early loss of *p*. 1, and the reduction of the incisors to $\frac{2-2}{2-2}$ in both jaws: in the extinct Hippopotamus of India *p*. 1 was longer retained, and the

* "Ces racines et les pédicules qui leur servent de noyaux s'alongent ensuite par deux raisons: d'abord les progrès des lames de substance osseuse qui, s'alongeant toujours, forcent la dent à s'élever et à sortir de l'alvéole; ensuite l'épaississement du corps de la dent par la formation des couches successives qui, en remplissant le vide intérieur, n'y laissent presque plus de place pour le noyau gélatineux, et le refoulent vers l'intérieur des tubes des racines." Annales du Muséum, viii. 1807, p. 108; Ossem. Fossiles, 1834, p. 527.

* Ossemens Fossiles, 4to.; Divers Mastodontes, pl. iii. *fig*. 2.

† Ossemens Fossiles de Darmstadt, 1835, pl. 1.

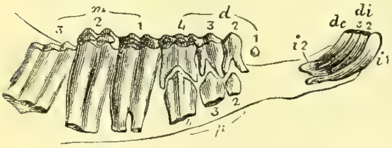
‡ Odontography, pl. 144, *fig*. 11, *d*. 3

incisors were in normal number $\frac{3-3}{3-3}$; whence the term *Hexaprotodon* proposed for this interesting restoration by its discoverers, Cautley and Falconer.

I have before remarked that the even-toed or artiodactyle *Ungulata* superadd the characters of simplified form and diminished size to the more important and constant one of vertical succession in their premolars. These teeth in the Ruminants, *e. g.* (*fig.* 580., VII., Moschus, *p.* 2, 3, 4), represent only the moiety of the true molars, or one of the two semi-cylindrical lobes of which those teeth consist, with at most a rudiment of the second lobe, as Cuvier very accurately describes *, and F. Cuvier figures in pl. 94. of his useful work, "Dents des Mammifères." An analogous morphological character of the premolars will be found to distinguish them in the dentition of the genus *Sus* (figured in my "Odontography," pl. 140., *figs.* 1 and 2), in the Hippopotamus (ib. pl. 143.), and in the *Phacochœrus* (ib. pl. 141.), where the premolar series is greatly reduced in number: yet this instance of a natural affinity manifested in so many other parts of the organisation of the artiodactyle genera has been overlooked in F. Cuvier's work above cited, although it is expressly designed to show how such zoological relations are illustrated by the teeth. Confiding in the accuracy of the Baron Cuvier's division of the hoofed quadrupeds into "Pachyderms" and "Ruminants," M. F. Cuvier separates the non-ruminant Artiodactyles from the ruminant genera of the same natural division by interposing the Tapir, Hyrax, Rhinoceros and Elephant; whilst the horse, which, in the size and complexity of its premolars, as well as in many other characters, agrees closely with the other perissodactyle Pachyderms, is placed in close juxtaposition with the Ruminants.†

Most of the deciduous molars of the Ruminants resemble in form the true molars; the last, *e. g.* (*fig.* 593., *d.* 4), has three lobes in the lower jaw ‡ like the last true molar (*m.* 3.). They

Fig. 593.



Permanent and deciduous teeth, Sheep (Ovis). (*Lower jaw.*)

are three in number on each side, and, being succeeded by as many premolars, the ordinary permanent molar formula is $p. \frac{3-3}{3-3}$, $m. \frac{3-3}{3-3}$: but there is a rudiment of *d.* 1 in the embryo fallow-deer, and in one of the most ancient of the extinct Ruminants (*Dorcatherium*, Kaup) the normal number of premolars was fully developed.

Sufficient, it is hoped, has been adduced to prove that the molar series of the Diphyodonts is naturally divisible into only two groups, premolars and molars; that the typical number of these is $\frac{4-4}{4-4}$, $\frac{3-3}{3-3}$; and that each individual tooth may be determined and symbolised throughout the series, as is shown in the instances under cut 580. If anything were wanting to prove the artificial character of a three-fold division of these teeth, and the futility of any other classification than that founded upon development, it would be afforded by the attempt to determine the homologous teeth which is exemplified by the dotted line which traverses the series, and which crosses the teeth distinguished by the name "principales" in the great "Ostéographie and Odontographie" now in course of publication by Prof. de Blainville.

This author abandons the classification of the molar series adopted by the Cuviers, without assigning his objections to it; and proposes another, in which he divides the series into "avant-molaires, principales, and arrière-molaires;" he exemplifies this division by the human dentition, in which the five grinders on each side of both jaws are formulised as "deux avant-molaires, une principale, et deux arrière-molaires." *

With regard to the characters of these kinds of teeth, the avant-molaires are "simple or complex," the principale is "trenchant," and the arrière-molaires are "tuberculous." † But as shape is not a constant character, especially in the "principale," the author proposes another from its position, describing it as "being implanted below the root of the zygomatic process of the maxillary bone" in the upper jaw; and stating that the tooth which opposes it below, and is in advance of it, or crosses in front of it, is the lower "principale."

In defining the dentition of the genus *Felis* ‡, M. de Blainville accordingly assigns 1 "avant-molaire," 1 "principale," and 2 "arrière-molaires" in the upper jaw; and 1 "avant-molaire," 1 "principale," and 1 "arrière-molaire" in the lower jaw. In another part of the same work §, he, however, proposes another formula, viz., 2 "avant-molaires," 1 "principale," and 1 "arrière-molaire" above; 1 "avant-molaire," 1 "principale," and 1 "arrière-molaire" below; but, taking either of these determinations, or the dental formulæ which he assigns to other carnivorous genera, and comparing them with his formula of the

* Ossemens Fossiles, 4to, tom. iv. p. 6.

† See my "Remarks on the Classification of the Hoofed Quadrupeds" in "Quarterly Journal of the Geological Society," May, 1848.

‡ When, therefore, the third grinder of the lower jaw of any new or rare Ruminant shows three lobes, the crowns of the premolars should be sought for in the substance of the jaw below these, and above their opponents in the upper jaw; and thus the true characters of the permanent dentition may be ascertained.

* Ostéographie, tom. i. p. 43.

† Ib. p. 43.

‡ Ostéographie des Carnivores, p. 69.

§ Ostéographie des Félis, p. 55.

molar series in the Quadrumana and Man, we find that a tooth which displaces and succeeds a milk-tooth in one species is made the homologue of a tooth, which, in Man and Quadrumana, rises above the gum without displacing any predecessor: in other words, the "principale" is a premolar in certain genera, and a true molar in other genera. I may refer to my Paper on the Classification of the Molar Teeth in the "Annales des Sciences,"* and to the concluding pages of the chapter on the teeth of the Carnivora in my "Odontography" (p. 514), in proof that a "molaire principale" does not exist in nature; that the characters by which it is defined by M. de Blainville are artificial; and that they fail in their application to determine the teeth in the series of placental Mammalia with deciduous and permanent teeth.

In the series of figures, *fig.* 580., the continuous line traverses the tooth or its homologue, in Man and the Ruminant, which Cuvier distinguished as the "molaire carnassière:" the dotted line traverses that tooth which M. de Blainville distinguishes as the "molaire principale:" the letters and numbers symbolise the teeth and indicate their individual homologies, and the binary division of the molar series, which it has been one object of the present Article to illustrate. I shall conclude it by showing how these symbols may be applied to the exposition of facts in the comparative anatomy of the teeth, and for that purpose select the complex and intricate subject of the succession of the teeth in the kangaroo.

The chief modifications of the marsupial dentition are described and illustrated in the article MARSUPIALIA (Vol. III. pp. 258—298.). When that volume was published I had not had the means of tracing the period and order of the development and succession of the entire series of teeth in any of the marsupial genera. The first of the five grinding teeth on each side of the jaws of the wombat had shown, by its displacing a milk-tooth vertically, that it was a premolar; and the adjoining molar, by its earlier development and use, was plainly the first of the four true molar teeth. In the carnivorous and insectivorous families, the marked difference of form and size of the last four teeth from those intervening between them and the canines, had also induced me to class them as true molars, although I had not got the developmental evidence of the fact, except in the case of the Kangaroos and Potoroos (*Macropus* and *Hypsiprymnus*). The analogy, however, seemed to be sufficient to justify the generalisation that the Marsupial differed from the Placental Diphyodont mammals in having four true molars, *i. e.*, $m. \frac{4-4}{4-4}$ instead of $m. \frac{3-3}{3-3}$; and also that they differed in having only three premolars, *i. e.* $p. \frac{3-3}{3-3}$ instead of $p. \frac{4-4}{4-4}$; the typical number of the grinding series, $\frac{7-7}{7-7}$, being the same. The genus *Myrmecobius* offered the most remarkable exception here, as the Manatee had done in the placental series, in the increased number of the grinding teeth, *e. g.* to $\frac{8-8}{9-9}$ or $\frac{9-9}{9-9}$, which, according to the shape of the crowns, were divided, in the *Myrmecobius*, into $p. \frac{3-3}{3-3}$, $m. \frac{6-6}{6-6}$; but the order of development and succession may show that the number of premolars is greater, and that of the true molars less. The probably marsupial *Thylacotherium* or *Amphitherium* from the Oxford oolites — the most ancient of all known mammals — had as many as twelve teeth in each molar series, besides a canine and three incisors, and by their form I have grouped them as: $i. \frac{3-3}{3-3}$, $c. \frac{1-1}{1-1}$, $p. \frac{6-6}{6-6}$, $m. \frac{6-6}{6-6}$.*

An interesting field of observation still remains open in regard to the period and order of developement of the deciduous and permanent teeth, in the different carnivorous, omnivorous, insectivorous, and frugivorous Marsupials. At present I have ascertained the required facts only in the herbivorous family (*Poephaga*).

The permanent dental formula of both the *Macropodidæ* and *Hypsiprymnidæ* is, $i. \frac{3-3}{1-1}$, $c. \frac{1-1}{0-0}$, $p. \frac{1-1}{1-1}$, $m. \frac{4-4}{4-4} = 30$. The canines, which are confined to the upper jaw, are small or minute when retained; and disappear after being represented "en germe" in most of the true kangaroos.

The deciduous dentition of the great Kangaroo (*Macropus major*) is, $i. \frac{3-3}{1-1}$, $c. \frac{1-1}{0-0}$, $\frac{2-2}{2-2} = 18$. The canines are rudimental, and are absorbed rather than shed. The deciduous incisors are shed before the young animal finally quits the pouch: when this takes place, the dentition is:—

$$i. \frac{1-1}{1-1}, d.m. \frac{2-2}{2-2} = 12;$$

the upper incisors being *i.* 1, the molars *d.* 3 and *d.* 4 of the typical dentition. This stage is exemplified in the lower jaw at A, *fig.* 594. The next stage shows the acquisition of *i.* 2 in the upper jaw, and *m.* 1 in both jaws, and the formula is:—

$$i. \frac{2-2}{1-1}, d.m. \frac{2-2}{2-2}, m. \frac{1-1}{1-1} = 18. \text{ (B, \textit{fig.} 594.)}$$

At one year old, the dentition is:—

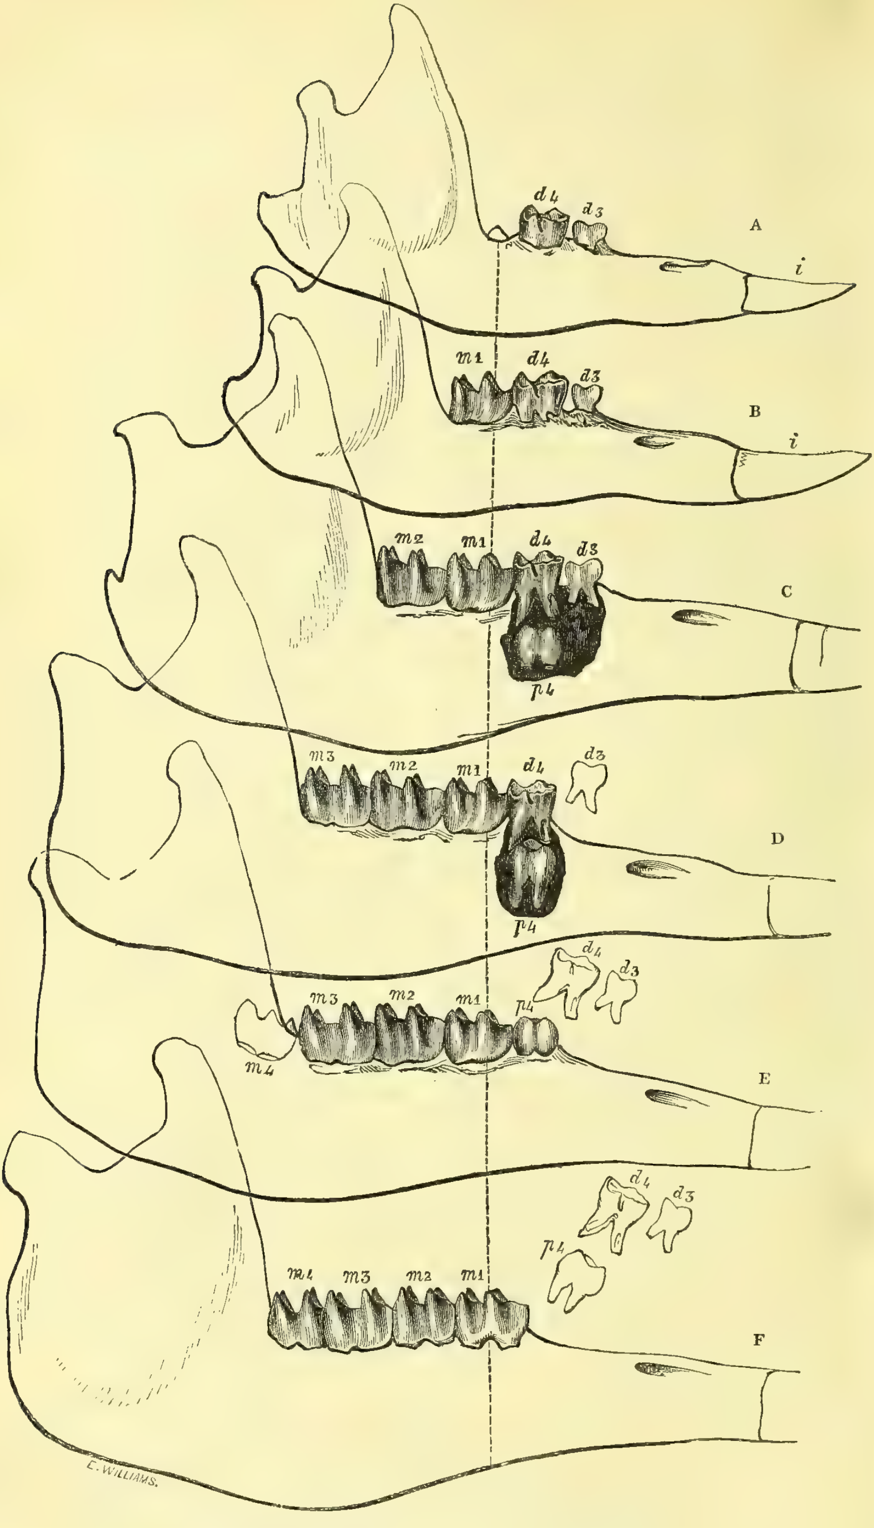
$$i. \frac{3-3}{1-1}, d.m. \frac{2-2}{2-2}, m. \frac{2-2}{2-2} = 24;$$

the additional teeth being *i.* 3 and *m.* 2 (C, *fig.* 594.; in which the demonstration of the true deciduous character of *d.* 4 and *d.* 3 is shown by the germ of their vertical successor,

* Tom. iii. (1845), p. 116.

* Odontography, p. 376, pl. 99.

Fig. 594.



Progress and change of dentition, Kangaroo (Macropus).

p. 4, which is exposed in the substance of the jaw). The next stage is the shedding of *d*. 3, and the acquisition of *m*. 3 (D, *fig*. 594.). Then *d*. 4 is shed by the ascent of *p*. 4 into its place (E, *fig*. 594.). Afterwards *m*. 4 is acquired, and, in the *Macropus gigas*, *p*. 4 is simultaneously pushed out (F, *fig*. 594.).

Thus, four individuals of this species may be found to have the same number of molars, *i.e.* $\frac{4-4}{4-4}$; two of these may seem, on a cursory comparison, to have them of the same shape, *e.g.*, like C and E, *fig*. 594.; or like D and F. In fact, to determine the identity or difference in such instances, it requires that the substance of the jaws be examined to see if the germs of successional teeth be present, as at *p*. 4, C and D, or at *m*. 4, E.

The result of such examination may be to show that not one of the four kangaroos with the *m*. $\frac{4-4}{4-4}$ had the same or homologous teeth. The four grinders, *e.g.*, may be—

d. 3, *d*. 4, *m*. 1, *m*. 2; as in C: or,
d. 4, *m*. 1, *m*. 2, *m*. 3; as in D: or,
p. 4, *m*. 1, *m*. 2, *m*. 3; as in E: or,
m. 1, *m*. 2, *m*. 3, and *m*. 4; as in F.

But the change does not stop here: as age advances, *m*. 1 is shed, and the molar series is reduced numerically to the condition of B; but, instead of *m*. 1, *d*. 4, and *d*. 3, it consists of *m*. 2, *m*. 3, *m*. 4.

Finally, *m*. 2 is shed, and the dentition is reduced to the same numerical state as at A, *fig*. 594.: the teeth, however, being *m*. 3 and *m*. 4.

The order here described is not precisely that which is followed in some of the smaller species of kangaroo. In *Macropus Benettii*, *e.g.*, the acquisition of *m*. 3 is not accompanied by the shedding of *d*. 3, but the molar series is numerically $\frac{5-5}{5-5}$: so, likewise, in this species, the acquisition of *m*. 4 is not accompanied by the displacement of *p*. 4; and a molar series of $\frac{5-5}{5-5}$ is long retained; but, at the earlier period cited, the teeth are:—

d. 3, *d*. 4, *m*. 1, *m*. 2, and *m*. 4:

and, at the later period, they are:—

p. 4, *m*. 1, *m*. 2, *m*. 3, and *m*. 4.

These symbols, it is hoped, are so plain and simple as to have formed no obstacle to the full and easy comprehension of the facts explained by means of them. Had those facts been described in the ordinary way, by means of verbal phrases or definitions of the teeth,—*e.g.*, "the second deciduous molar, representing the fourth in the typical dentition," instead of *d*. 4, and so on,—the description would have occupied much more space, and have levied such a tax upon the attention and memory, as must have tended to enfeeble the judgment, and impair the power of seizing and appreciating the results of the comparisons.

Each year's experience strengthens my conviction that the rapid and successful progress of the knowledge of animal structures, and of the generalisations deducible therefrom, will be mainly influenced by the determination of the nature or homology of the parts, and by the concomitant power of condensing the propositions relating to them, and of attaching to them signs or symbols, equivalent to their single substantive names. In my work on the "Archetype of the Skeleton," I have denoted most of the bones by simple numerals, which, if generally adopted, might take the place of names; and all the propositions respecting the centrum of the occipital vertebra might be predicated of 1 as intelligibly as of "basioccipital."

The symbols of the teeth are fewer, are easily understood and remembered, render unnecessary the endless repetition of the verbal definition of the parts, harmonize conflicting synonyms, serve as a universal language, and express the author's meaning in the fewest and clearest terms. The entomologist has long found the advantage of such signs as ♂ and ♀, signifying male and female, and the like; and it is time that the anatomist should avail himself of this powerful instrument of thought, instruction, and discovery, from which the chemist, the astronomer, and the mathematician have obtained such important results.

(*R. Owen.*)

TEMPERAMENT. Although all individuals of the same species are composed of the same tissues, consisting of the same elements both proximate and ultimate, and agreeing in all essential points of chemical constitution, yet there exist between certain groups of them, sometimes in the most striking degree, differences not only in the physical powers and actions of their frames, but also in their mental qualities. These differences are referrible only to peculiarities in the constitution of an individual, or in other words, to peculiarities in the quality of his solids and fluids, which are of a nature so recondite that we cannot detect them by any chemical or anatomical means, and we appreciate them only by the character with which they impress the physical and, to a certain extent, mental actions of the individual in which they exist. To express this character in one word physiologists employ the term *temperament*.

The use of this word is of very ancient date. We trace it as far back as the time of Galen, who broached the doctrine that the blood consisted of four humours, corresponding to the four elements; these were respectively designated *bilis*, *sanguis*, *atra bilis*, *phlegma*. Nunc, says Haller, ex ejusmodi quatuor humoribus sanguinem aiebant *temperari*, justamque omnium principiorum commistionem perfectissimum *temperamentum* efficere; si vero aut sanguis supra legitimam suam quasi dosin abundaret, sive bilis, sive terra atrave bilis, sive phlegma, quatuor tunc simplicia et præcipua temperamenta aiebant oriri, a bilis abundantia *cholericum*, ab aquæ ubertate *phlegmaticum*, a sanguinis aucta portione *sanguineum,* et denique a copia atræ bilis *melancholicum.**

This view of the doctrine of temperaments prevailed in the schools down to the time of Cullen, and we find that able and thoughtful physician thus expressing himself upon the subject: "The ancients very early established a distinction of temperaments which the schools of physic have almost universally adopted ever since, and appears to me to be founded on observation. I am very much of opinion, that we can perceive a combination of a particular state of the chief circumstances of the economy to take place very steadily in certain persons, and thereby to form at least two of the temperaments assigned by the ancients."†

The temperaments, the existence of which seems most consistent with observation, are those admitted by Cullen, namely, *the sanguineous* and the *melancholic*, the *phlegmatic* being a degree or modification of the sanguineous, and the *choleric* of the melancholic.

It is reasonable to expect an infinite variety as regards the extent to which the characteristic marks of the temperaments are manifested in various individuals. Taking examples which afford good indications, the two temperaments above referred to may be described as follows, after Cullen.

Individuals of the sanguine temperament have the quantity of fluids in the body large in proportion to the solids, the habit of body soft and plump, after the period of manhood disposed to obesity, and at all times, readily sweating upon exercise, the skin smooth and white, the hair soft, generally of a pale colour or from thence passing through different shades to a red; the complexion ruddy, the eyes commonly blue; the strength of the whole body is moderate, and the mind sensible, irritable, cheerful, and unsteady. The most exquisite examples of this temperament are found in men from the time of puberty to that of manhood, and in women. In both sexes the characteristics of the temperaments are far less manifest in old age.

In persons of the melancholic temperament the habit of the body is rather hard and meagre, the quantity of fluids in the whole system moderate in proportion to the solids, the simple solids firm and dense, the hair hard, black, with a tendency to curl, the skin coarse, of a dun colour, with a corresponding complexion, the eyes very constantly black, the strength considerable, the mind slow, disposed to gravity, caution and timidity, with little sensibility or irritability, but tenacious of all emotions once excited, and therefore of great steadiness. This temperament is most completely formed in advanced life, but the characters of it appear often very early.‡

By some writers a *nervous* temperament is admitted, the prominent characteristic of which consists in a great excitability of the nervous system, and a predominance of emotional impulses over the influence of the will. Individuals of this temperament are generally fidgetty and restless, take but little sleep, and are anxious about trifles; they are called "creatures of impulse;" their emotions are easily excited, and often not readily subdued. In persons of this temperament, when labouring under disease, phenomena referrible to the nervous system are very apt to complicate and often to obscure the morbid actions. This temperament, however, cannot be said to exist apart from the sanguineous or melancholic: it always accompanies either one or the other, most frequently the former, and the most exquisite examples of it are found in the female sex.

In looking at the physical conditions of the best-marked examples of the sanguine and melancholic temperaments, it is important to ascertain whether any one property or quality stands out more prominently than the rest, which might seem to give to the whole economy of the individuals its peculiar cast. It appears to me that there is no single physical property which is so closely associated with difference of temperament as variety in the quantity, and perhaps also in the kind, of colouring matter or pigment, evinced by the colour of the hair and skin, and influencing also the colour of the eyes, and of the blood, and of the nervous centres.

Individuals of the melancholic temperament exhibit in their various tissues a considerable amount of pigment, as shown by the dark colour, generally black, of the hair and eyes, while on the other hand those of the sanguine temperament are deficient in colour, having light hair, blue or grey eyes, and fair or white skins. Observations are yet wanting, in sufficient number, to determine the relative amount of colouring matter in the blood of individuals of each of these temperaments, or to ascertain whether it is characterised by any peculiar chemical qualities. It seems highly probable that the amount and kind of colouring matter in the skin, hair, and eyes, as well as of that in some of the secretions, as bile, urine, &c. is influenced by the amount and kind of the hæmatine.

The xanthous and leucous races of man inhabiting for the most part cold or temperate climates, afford the most numerous examples of the sanguine temperament, while the melano-comous or dark races found chiefly in warm climates are mostly of the melancholic temperament. And those individuals of the xanthous and leucous races, which in physical characters approach most nearly to the dark races, as by the existence of a large quantity of dark pigment in their tegumentary tissues, are of the melancholic temperament, whilst the light-coloured members of the xanthous races are prone to exhibit the characters of the sanguine temperament.

If it be admitted that a constant connection exists between colour and temperament, as I think is sufficiently obvious, it would follow that the nature of the temperament is determined by certain peculiarities in the physical

* Haller, El. Physiolog. lib. v. sect. 4.
† Mat. Med.
‡ Cullen, loc. cit.

condition of the frame. These peculiarities react to a certain extent upon the mind, and more or less aid or clog its workings, but certain powers and modes of action of the mind are by no means so constantly associated with certain states of body, as to connect the mental and bodily states as cause and effect. It is true that the sanguine temperament is generally accompanied by a mind exhibiting certain characters, but the exceptions to this are so numerous that we cannot assign the corporeal state as the cause of the mental — nor *vice versâ*. Bodily peculiarities are infinitely more frequently inherited than mental, — the powers and activity of the mind are greatly determined by education and training; but those qualities of body which give a character to its temperament are born with it; and although they may be modified by external influences, they are yet at all times sufficiently distinct to prove them to be inherent physical properties of the entire organism.

At the same time it seems reasonable to admit that the mind has its temperaments, as the body has, and in a great measure independently, and the terms, sanguine, melancholic, phlegmatic, and choleric, may be severally applied to them, according as the emotions and feelings, and the intellectual actions vary in their modes and degrees of developement, and in their rate of working.

(*R. B. Todd.*)

TEMPORO-MAXILLARY ARTICULATION.

TEMPORO-MAXILLARY ARTICULATION.—Under this heading I propose to give a brief account of the jointing of the lower maxilla to the cranium. This joint cannot, of course, be identified out of the *vertebrata*. The mandibles and maxillæ of the *articulata* are not homologous with the jaws of vertebrate animals, and the slit of their mouths is placed vertically not horizontally.

In the *human subject*, as in all *mammalia*, this articulation takes place between the squamous portion of the temporal (*squamosal*) and the inferior maxillary bones. The description of the anatomy of the human temporo-maxillary joint comprises, therefore, that of the diarthrodial articular surfaces of those bones, and also of the following parts: viz., the interarticular fibro-cartilage, the two synovial sacs, the external and internal lateral and other ligaments, and part of the insertion of the external pterygoid muscle.

Bones. — The articular condyle of the lower jaw is sub-cylindroid in form, its length from side to side being greater than its antero-posterior measurement. The axis of this cylinder, however, is set neither directly from side to side, nor yet exactly level, its inner part being posterior to and below its outer; so that if the axes of the two condyles were produced inwards till they met, they would form an angle in doing so, which would point downwards and backwards, — reaching the anterior margin of the foramen magnum. The cartilage that encrusts this condyle extends further down behind than in front.

The surface to which this condyle is (mediately) articulated forms a part of the glenoid fossa, and is situated just below the base of the zygomatic process of the temporal bone, between its roots. It has such form as, in respect of the set of its axis, and its tranverse measurement, pretty accurately fits the condyle. It has, however, a greater antero-posterior extent, in accordance with the capability which this joint normally possesses, in addition to the usual ginglymoid motion, of an antero-posterior gliding to and fro of the condyle — a kind of normal dislocation. The glenoid fossa of the temporal bone contains a portion of the parotid gland, as well as the condyle of the inferior maxilla; the former occupies that portion of it which is posterior to the glasserian fissure, whilst that part which is anterior to the glasserian fissure, is lined with cartilage for the articulation of the latter. In man there is usually no bony ridge bounding this articular surface posteriorly, such as is generally found in the lower mammalia.

The ridge that bounds it anteriorly is formed by the inferior root of the zygoma, and the cartilage is continued some way on to this ridge. Externally it is limited by a tubercle on the zygoma, which serves for the attachment of the external lateral ligament of the joint.

Interarticular fibro cartilage. — This is a thin disc or meniscus, oval or sub-oblong in form, concave below and convex above, thus capping the condyle, thicker at the edges than in the middle, where it is not unfrequently thinned away even to perforation. It differs from all the other fibro-cartilages in having muscular fibres inserted into it; namely, a portion of those of the external pterygoid. This insertion takes place along its anterior border, and by it the fibro-cartilage is made to join in that normal amount of dislocation forwards, which as above stated, the condyle of the lower maxilla is capable of, as well as in the abnormal accidental dislocation of the jaw. It is further held in its place by the fibres of the external lateral ligament, and by the synovial bursæ of the joint.

Synovial Bursæ. — These are two in number, one above the interarticular fibro-cartilage and the other below it. The upper one is the larger and slacker, for it alone is concerned in the antero-posterior gliding of the joint. The two sacs, of course, communicate and are reduced to one when the interarticular fibro-cartilage is perforated in the centre.

Ligaments.—There is only one ligament in immediate relation with the temporo-maxillary joint, namely, the *external lateral.* This is a small ligament, broader above than below, situated at the outside of the joint; attached above to the tubercle situated at the point of divergence of the roots of the zygoma; and directed downwards and backwards to the outside of the neck that supports the condyle of the lower jaw. Midway in its passage from the one to the other it is attached by its inner aspect to the interarticular fibro-cartilage.

The *internal lateral ligament* is a long thin slip extending from the spinous process of the sphenoid, and the neighbouring parts of the temporal bone to the fore part of the lip of the inferior dental canal. It lies behind the external pterygoid muscle, by the origin of which its cranial attachment is concealed, and it is separated from the temporo-maxillary joint by a considerable space through which pass the internal maxillary artery and vein, giving off their middle meningeal and inferior dental branches, which indeed are conducted, the former to the foramen spinosum of the sphenoid, the latter to the inferior dental canal, by the ligament in question.

Numerous stray fibres of ligamentous tissue strengthen the synovial sacs of the temporo-maxillary joint, forming a kind of *capsular ligament.*

That process of the cervical fascia, which is called the *stylo-maxillary ligament*, is generally enumerated as one of the ligaments of this joint. It extends from the styloid process to the lower part of the ramus of the jaw, separating the parotid from the submaxillary gland, and affording attachment to the stylo-glossus muscle. The condyle of the lower jaw depends for the maintenance of its normal apposition to the temporal bone much more upon the masseter, temporal and pterygoid muscles than upon these small ligaments; by these, however, its astero-posterior gliding is indifferently tethered.

Muscles. — The *external pterygoid-muscle*, proceeding backwards and outwards from its origin, is mainly inserted into the front of the neck that supports the maxillary condyle, the upper part of it, however, is inserted into the interarticular fibro-cartilage, which thereby is drawn forward along with the condyle when this muscle acts. This insertion is tendinous.

Motions of the joint. — The temporo-maxillary joint admits of a ginglymoid motion in the vertical direction, by which the mouth is opened and shut. This motion must of necessity always take place in the joints of both sides at the same instant. It also admits of a horizontal antero-posterior gliding motion, in which the joint of one side only may be mainly concerned. In the human subject the front teeth of the lower jaw, in most cases, are not exactly opposed to those of the upper jaw—that is, the summits of the one set are not applied to the summits of the other — in the ordinary position of the mouth, either when at rest or engaged in mastication. The lower incisor teeth are usually posterior to the upper. But when we bite with the front teeth we bring the upper and lower set into apposition by thrusting forward the lower jaw : in this act both joints are similarly concerned. We can also execute a grinding motion from side to side, and this is done by thrusting forward one condyle whilst the other merely revolves on the axis of its neck.

The jaw is *elevated* or closed by the temporal, masseter, and pterygoid muscles. The pterygoid, chiefly the external, are the agents in *protruding* it. These latter are antagonised by the elevating and also by the depressing muscles. The chief *depressor* of the lower jaw is the digastric, as is clearly shown by its comparative anatomy, but all those which extend from the chin to the hyoid bone are capable of, and occasionally do assist in performing this act.

The majority of the muscular fibres that elevate the jaw arrive at their insertion into it from before backwards; thus the masseter has a kind of twist in the arrangement of its fibres, so that those which arise most anteriorly are inserted very conspicuously furthest back, whilst the remainder proceed directly downwards or slightly forwards; a considerable portion of those of the temporal, namely, those which arise from the anterior part of the temporal fossa, run *backwards* to their insertion into the coronoid process. The use of this arrangement seems, upon a careful consideration of the mechanics of the question, to be the application of the elevating or closing force in a more favourable direction, not, as might seem at first sight, the protrusion of the lower jaw — that is amply effected by the *pterygoideus externus.*

Abnormal conditions of the temporo-maxillary joint.—*Accidents.*— The condyle of the lower jaw can only be *dislocated* in one direction, namely forwards. In this accident the condyle slips forward over the inferior root of the zygoma, and is then drawn somewhat upwards within the zygomatic arch. The inter-articular cartilage is carried with it. This usually happens to the joints of both sides, but occasionally one condyle only is dislocated. It is usually produced by the action of the muscles when the mouth is very widely opened, as in yawning, or more especially in biting a very large object, such as a large apple.

When both the condyles are dislocated, the lower jaw is thrust forwards and cannot be retracted. The mouth is widely open and the patient is unable to close it. The power of swallowing is lost, and the saliva, the secretion of which is probably increased, flows from the mouth involuntarily. Articulation is difficult, owing to the impossibility of making the labial sounds. There is a conspicuous depression beneath the zygoma just in front of the ear, and a flatness in the masseteric region. The coronoid process is much depressed, and forms a visible protuberance beneath the zygoma, and, as first observed by Mr. Adams of Dublin, there is a prominence in the temporal region between the eyebrow and the ear, produced by the posterior fibres of the temporal muscle being pushed up by the condyle in its new position.

If this dislocation remains unreduced, the parts, as in most other dislocations, gradually accommodate themselves to their new position, so that the power of articulation and deglutition is re-acquired, the mouth can be closed, and a considerable amount of motion is regained, but the chin remains abnormally thrust forwards, and there is always a depression in the position normally occupied by the condyle.

When one condyle only is dislocated, the chin is thrust forwards and towards one side —that, namely, on which the condyle remains in place. The coronoid process of the dislocated side forms a prominence even more conspicuous than when both condyles are displaced, but the mouth is not so wide open. There is, of course, the same depression in front of the ear, and the same flatness of the masseteric region.

Congenital malformation. Dr. R. W. Smith of Dublin, in his Treatise on Fractures and Dislocations,* gives a detailed account of the dissection of a highly interesting case of "Congenital luxation of the inferior maxilla." The malformation affected one side only, — the right,— and consisted mainly of an absence, or arrest of development of the condyle, the only vestige of which was a small process hooked inwards at its apex. This process did not touch the temporal bone by a quarter of an inch, and neither it nor the surface opposite to it presented any articular cartilage, but were both simply invested with periosteum. There was no trace of an interarticular fibro-cartilage, nor of a synovial sac, and the external lateral ligament sloped downwards and forwards instead of downwards and backwards. The glenoid cavity did not exist, or rather the inferior root of the zygoma, which really forms the glenoid cavity, was not developed. There was conspicuous atrophy of the whole of this side of the face in respect of the bones — temporal, right half of the body and right ramus of the inferior maxilla, malar, superior maxillary, and even the right half of the sphenoid, — and muscles, but the nerves were as large as their fellows. The most remarkable of the peculiarities of the surrounding parts, and that which clearly demonstrated the abnormal condition not to be the result of injury or disease, was an extreme shortness of the zygomatic process of the the temporal and a compensatory unusual length of that of the malar bone. The former was only half an inch long, whilst the latter was nearly twice as long as that of the other side. During the lifetime of this patient, who was an idiot, it was observed that one side of his countenance did not match the other, and that the disparity was much increased when he opened his mouth. He was often observed to have spasmodic twitching of the abnormal side of his face.

Disease. — *Chronic rheumatic arthritis* occasionally affects this articulation. Both joints are usually affected by it, but sometimes it attacks the joint of one side only. It is most common in elderly subjects. When it attacks the young or middle aged, it is more rapid, accompanied with more pain, and more likely to involve the neck of the condyle and the ramus of the jaw. The pain is often very severe but variable, apparently influenced by meteorological changes. The lymphatic glands in the neighbourhood of the diseased joint are much prone to enlargement; and sometimes the enlarged condyle can be felt as a bony tumour just in front of the ear. The chin is thrust forward, mesially when both joints are affected, and towards the healthy side, as well as forwards, when only one is diseased. The motion of the jaw is considerably impaired. On dissection, the condyle, in cases of this affection, is generally found to be large and broad, but sometimes conical, rough, and devoid of cartilage. Ivory or porcellanous deposit, so common in other joints when affected with chronic rheumatic arthritis, is but rarely met with in this; those abnormal ossific concretions in and around the joints, which are so constantly met with in the disease in question in other situations, have also never been found in the temporo-maxillary joint. The interarticular fibro-cartilage had disappeared in every case of this affection which has been dissected and published. The glenoid cavity is enlarged, divested of its articular cartilage, and presents a roughened, abnormal surface. All indication of the disease stops suddenly at the glasserian fissure, and at the spheno-temporal suture, and the enlargement of the glenoid cavity takes place at the expense of the lower root of the zygoma which generally becomes entirely absorbed.

In the report of the proceedings of the Pathological Socety of London in the Medical Gazette of November 30. 1849, there is an account of a highly interesting case of *necrosis* of the condyle, back part of the ramus, and angle of the lower jaw in a *scrofulous* boy. The portion of necrosed bone, which was exhibited to the society, was removed many years before, by Mr. Keate, who also had examined the patient, grown to a healthy man, two years before the date of the communication. As far as could be ascertained by external investigation, the lost portion of bone had been perfectly restored. There was no deformity, and no impairment of motion. There are two other similar cases on record; one by Desault, in which the whole ramus, with the condyle and coronoid process, were removed, the other by Mr. Syme, in which the condyle and ramus were necrosed. In both these cases, also, the lost bone was perfectly restored to all external appearance, but there is no record of a dissection of such a case. In some cases which are on record, where the whole of the lower jaw, with both its condyles, has been removed, its place has been supplied by condensed fibrous tissue, but there has been no reproduction of bone.

Anchylosis of the temporo-maxillary joint is a very rare occurrence. There is, however, one specimen of it in the Pathological series of the Museum of the London College of Surgeons. The fusion of the two bones is complete, as is shown in the preparation by a vertical, side to side, section through the situation of the quondam joint. This section shows that a perfectly normal-looking cancellous structure, shelled over by a layer of dense osseous tissue, is continued from the temporal to the inferior maxillary bone, and exhibits no

* A Treatise on Fractures in the Vicinity of Joints and on Certain Forms of accidental and congenital Dislocations. Dublin, 1847. 8vo.

manner of trace to indicate where the joint once was. In fact this anchylosis had existed for fifty years before the death of the patient. No record is preserved of the cause of it. The joint of one side only is anchylosed, but that of the other side is much altered in form. An abnormal tubercle of bone projects downwards from the middle of the glenoid cavity and is received into an abnormal excavation or alveolus in the middle of the condyle. The lower jaw is much wasted in size, and has lost all its teeth save the two front incisors. The upper jaw bones are thin and light.

The motion of the lower jaw is often lost owing to an affection not immediately connected with the joint itself. When, as often happens in scarlatina, cancrum oris, &c. there is extensive sloughing of the inside of the cheeks, the cicatrices resulting from the healing of the great wounds contract, and form bands, extending from the upper to the lower jaw, so strong and unyielding that the muscles which open the mouth are unable to antagonise them.

Comparative Anatomy.—If a palæontologist were asked what fragment of a vertebrate skeleton, speaking generally for all vertebrata, would give him most information as to the status and affinities of the animal to which it belonged, he would most probably answer — the articular portion of the lower jaw or the articulation that receives it. Of the convex and concave surfaces which go to form this articulation, in all the *mammalia* the *convexity* is on the inferior maxilla, and the concavity on the squamosal bone, whilst in the three other vertebrate classes the reverse is invariably the case — the concavity is on the inferior maxilla, the convexity on the bone that articulates with it.

The under jaw does not articulate with the same, or to speak more accurately, with the homologous bone in all vertebrate animals. In all the mammalia it articulates, as in man, with the squamous element of the temporal — the squamosal bone. In birds, reptiles, and osseous fishes it articulates with bones which are clearly the special homologues of the tympanic ring of the human subject. In cartilaginous fishes its articulation is with the pterygoid bone, the homologue of the human internal pterygoid plate. The Lepidosiren, in which so many other characters of the osseous and cartilaginous fishes are so curiously blended together, in strict accord with this circumstance, presents an instance of the pterygoid and tympanic bones contributing each a part — the former the inner, the latter the outer part, of the articular surface for the reception of the lower jaw.*

It is well worth while to stop here and review what is stated in the two preceding paragraphs. What is said is, really, this; — every animal that suckles its young has a convex articular surface to its lower jaw, whilst every vertebrate that lays eggs has a concave surface. Or this — every vertebrate animal that has hair upon it, that has a diaphragm, or an epiglottis, has a convex articular surface to its lower maxilla, whilst all vertebrates that are destitute of these have a concave surface. Or, again, all animals that suckle their young, and have diaphragms, hair, and epiglottides, present their squamosal bones for the articulation of their inferior maxillæ, whilst all in which the possession of these characters is negatived present for this articulation their tympanic. or, rarely, their pterygoid bones. Can any physiological reason be assigned for this? Can any final purpose, holding good in all, or in the majority of, instances, be shown to be served by this difference? I think none can. One cannot conceive but that it is a matter of perfect indifference whether the convexity is on this bone or that. Let us look once more to the facts. The bat that flies, but not the swallow, the whale that swims but not the cod-fish, the camel that walks the desert, but not the ostrich, the carnivorous lion, seal, and weasel, but not the eagle, penguin, crocodile, and shark, have convex articulations to their lower jaw and present to them their squamosal bones. Here then is a caveat for the physiologist. A character found in an animal may have no physiological signification,—no relation to external circumstances, nor even a functional connexion with, or dependence on other characters wherewith it coexists, perhaps invariably. It may be due to the status only of the animal. Physiologically independent it may exist in an animal only because other independent characters co-exist. It may be a *Syneilogy*, not a *Teleology*.

That certain independent characters invariably go together, which was so elaborately illustrated by Cuvier, is a fact of a high order, perhaps the twilight of some great truth. If future investigations should prove that truth to be progressive developement, towards which hypothesis the inquirer is, even now, tempted by so many striking facts, as well as by the admirable use that can be made of it as a scaffold theory, then we should say, and as making use of a scaffolding we may say it now, that certain characters are attained to at a certain stage in the chain of development, and, therefore, those are found coexisting which are proper to the degree of development to which the animal has arrived. Such characters I have been accustomed to call *Syneilogies* *, a word which at all events has the merit of referring only to a well known fact, without involving any hypothesis. To the palæontologist this "correlation of independent characters" † is, of course, invaluable, and for the purpose of arranging *natural* groups in the animal kingdom, these, so to speak, useless, or Syneilogical, characters are immeasurably more valuable than those modifications to meet special exigencies which are called teleologies.

Mammalia. — In all mammalia, except man, the articular surface on the squamosal bone is bounded posteriorly, or, in the rodents, inter-

* Owen.

† Cuvier.

nally, by a prominent ridge or process. This is the case in the higher *Quadrumana*, and there is an indication of it even in the lower races of mankind. In the *Carnivora* the condyle is in general extremely long, cylindroid, and its length is set, almost or quite directly from side to side, whilst the surface to which it is opposed is bounded by a very salient ridge fore and aft. This condition attains its acme in the *Badger*, where the salient ridges, especially the posterior, even arch over and surround the cylindroid condyle so much, that in the dry skull the lower jaw remains attached to the cranium without any artificial contrivance, and can be removed only by slipping each half out sideways when the symphysis has been disjoined. With such a joint there cannot, of course, be the usual lateral motion of the jaw. In the Rodentia, on the contrary, the long diameter of the condyle is directed antero-posteriorly, and is adapted to an antero-posterior groove, mostly bounded, internally and externally, by salient ridges. Hence that nibbling, antero-posterior motion of the jaw, which is so conspicuous in these animals, and with which their teeth and masticatory muscles are in such admirable relation. This only holds good in respect of the placental rodents. In that great *marsupial* rodent, the *Wombat*, the saliently arched, cylindroid condyles have the usual side to side and converging-behind set of their long diameters. The articular surface which is opposed to this condyle is placed, as in the placental rodents, on the zygomatic process, which in both runs almost directly outwards; instead, however, of being an antero-posterior groove it is a transverse convex cylindroid, describing a retreating curve ; so that in the temporo-maxillary joint of the wombat a cylindroid ridge is opposed to another cylindroid ridge, the one describing a salient, the other a retreating arch.* The articular facets of the temporo-maxillary joint in the *Ruminantia* approach more nearly to plane surfaces than in any other animals. The squamosal facet is bounded by a ridge posteriorly, but has no bony limitation in front. This is in relation with the extensive lateral movement of the jaw which these animals use in chewing the cud, and with the limited power of gaping which they possess. The rest of the mammalia present varieties in this joint which are extremely interesting, but an account of them would occupy more space than the limits of this work permit.

Aves. — In birds, as above stated, the articular surface of the lower mandible is concave, and is adapted to the tympanic bone, or, as the older ornithologists called it, the os quadratum.† The articular surface of the lower jaw presents two concave depressions. The tympanic bone is itself moveable, being articulated to the cranium by two diarthrodial joints, so that a bird's lower jaw is swung to the head by two moveable jointings.

Reptilia. — The evenly concave articular surface of a reptile's lower jaw is often contributed to by more than one of the osseous pieces which compose the inferior maxilla of the oviparous vertebrates. In the crocodile by two, in some chelonia by three of these pieces. The tympanic bone is articulated with the other cranial bones by suture, and is therefore immoveable, in the *Crocodilia* and *Chelonia*, but it is articulated with them by diarthrosis, and therefore moveable, in the *Lacertia*, *Ophidia*, and *Batrachia*. In some ophidia, as the *Python*, there being, properly speaking, no symphysis of the lower jaw, but instead of it an elastic ligament, holding the two halves together at the chin, one temporo-maxillary joint is capable of movement independently of the other. In the Batrachia, among their many fish-like characters is that of a dismemberment of the tympanic bone, which consists of an upper and a lower piece.

Pisces. — In the majority of fishes, the tympanic bone is represented by four separate pieces called epi-, hypo-, meso-, and præ-tympanic bones. These, further, bear upon their posterior edge three opercular bones, which were considered by Geoffroy St. Hilaire to be the homologues of the ossicula auditus, but are regarded by Prof. Owen as appendages, serially homologous with the costal appendages. The uppermost piece, the epi-tympanic, articulates by a diarthrodial joint with the mastoid, and the lowermost, hypo-tympanic, presents a diarthrodial convexity to the lower jaw. The four tympanic pieces articulate with one another, and with the opercular bones by the interposition of ligament, or rather membrane, connecting their thin adjacent edges together, so that the whole apparatus is capable of bilging outwards in the movements of respiration. In the eel tribe (*Murænidæ*) the number of tympanic bones is reduced to three, which is obviously an approach towards the two tympanic pieces of the Batrachia. The formation of the cranial part of the joint in question by the pterygoid and tympanic bones conjointly, in the *Lepidosiren* has been mentioned above. In the *Sharks* and *Rays* the tympanic pedicle descends upon that part of the pterygoid which forms the joint, but does not actually reach the articulation, the pterygoid being interposed. In these fishes, the super-maxillary and pterygoid pieces being confluent, and both bearing teeth, it appears at first sight that the whole upper jaw is formed by the former alone, consequently that the inferior maxilla is articulated directly with the super-maxillary ; such an articulation, however, never takes place in any animal.

The *interarticular fibro-cartilage* is constantly met with in *Mammalia*, but in neither of the other vertebrate classes.

Homology of the joint. — The joint in question is the articulation between the *pleurapophysis* and the *hæmapophysis* of the frontal vertebra. It is therefore serially homologous with the joint between the rib and the costal cartilage of mammalia, or the vertebral and sternal ribs of birds and reptiles.

* See Art. MARSUPIALIA, fig. 94.
† See Art. AVES.

The joints connected with the maxillary apparatus of some of the animals belonging to the three lower sub-kingdoms are, as was stated in the beginning, not homologous with this joint, although identical in function. For description of these parts see the articles ANNELIDA, ARACHNIDA, CEPHALOPODA, CIRRHOPEDA, CRUSTACEA, ECHINODERMATA, ENTOZOA, INSECTA, MYRIAPODA, and ROTIFERA.

(*S. R. Pittard.*)

TERATOLOGY. — Under this name, which we owe to Geoffroy St. Hilaire, we understand the doctrine of *congenital deformities.** In a scientific sense, it constitutes a part of Pathological Anatomy, and demands our interest as much as the knowledge of those other deviations from the normal state, which is ordinarily regarded as constituting that science. In fact, pathological anatomy comprises all the anomalies of the organization; those which occur during intra-uterine life are called *congenital*, and those which arise during extra-uterine life *acquired.* We refer to the former the imperfections of the primitive formation, or what we call monstrosities. They are those deviations of the organism which can be formed only in the earliest periods of gestation, or, at least, previously to the termination of the fœtal condition.

The opinions now held with respect to these malformations differ widely from the absurd notions which influence the descriptions given of them by Aldrovandi, Ambrose Paré, Licetus, Palfin, and Rueff. Formerly, indeed, each monstrosity was considered as the presage of some misfortune, the warrant of divine vengeance, the effect of witchcraft, &c. Lycosthenes used to go so far as to add to the description of each monster the picture of some calamity which was to be its sequel. To that opinion they owe their name, derived from the Latin verb *monstrare.*

Their ætiology was not less strange and incorrect. Rueff, in 1580, devoted a whole chapter to the inquiry, "An homines ex dæmonibus et rursus dæmones ex hominibus infantes concipere possunt?" and Casparus Schottus treated the subject in about the same style.†

They both give negative answers to the question, trusting to have proved by this means that monsters are not procreated by sexual intercourse of women with the devil. Other writers have endeavoured to explain the cause from copulation with brute animals, or with pregnant or menstruating women. Notwithstanding our more enlightened modern ideas on this subject, the origin of monstrous births remains still very mysterious. The opinions concerning it may be reduced to two main points: 1. To the original malformation of the germ; 2. To the subsequent deformation of the embryo by causes operating on its development.

I. *Original malformation of the germ.* — If, according to the opinions generally adopted at the present time, the germ may be considered as a product of secretion by the female organism, upon which the male sperm acts with its material and vital influence, we may suppose that this germ may be originally malformed, owing to some influence proceeding either from the female or from the male sex.

1. Such a primitive malformation of the germ seems to exist in those cases in which the same kind of monstrosity is repeatedly procreated by the same parents. The cause may be ascribed: —

a. To the mother. — It is a very important fact that, in such cases, various degrees of the same species of deformity are frequently produced in successive progression, so that the first born child is the most deformed; and in the following children the deformity progressively decreases, and finally disappears in the last born (G. Vrolik, Vering). Sometimes a deformity of the mother is communicated to her offspring; for instance, *congenital luxation of the femur.*

b. To the father. — Experience proves that a well-formed man may procreate with different women children with the same malformation (Meckel, Luber), and that a deformity of the father may be transmitted to the child (Burdach, Osiander). The last is however rare.

2. A second proof in support of the probability of an original malformation of the germ is found in hereditary deformities extending over more than one generation, viz. hare-lip, excessive number of fingers, *hypospadias*, &c.

3. A third proof may be deduced from the possibility that the ovarian ova in man and in the lower animals may be already malformed (Bischoff).

II. *Deformation of the originally well-formed germ.*— 1. It is said that this may be produced by mental impression of the pregnant woman, or what the German authors call *das Versehen.* But for this opinion no positive proof can be afforded. According to the observations published thereupon, and of which a great deal may be found in the learned article GENERATION of this *Cyclopædia*, all the supposed mental impressions, which have been considered as the cause of malformations, took place, with few exceptions, in the last stage of pregnancy.* And even in those cases in which an earlier period may be certified, we could object that the *post hoc* must not always lead to the conclusion *ergo propter hoc.* It is of some importance to appreciate the correctness of this

* From τέρας, monster; and λόγος, science.

† I. Rueffus de Conceptu et Generatione Hominis. Francof. ad M. 1580. P. Casparus Schottus e Societate Jesu, Physica curiosa, aucta et correcta, sive Mirabilia Naturæ et Artis. Lib. i. § xxii.

* See my publications in Tijdschrift v. Natuurlyke geschiedenis en Physiologie, d. iv. bl. 221, en tolgy. en Handb. d. Ziektch. Ontlurh. d. i. bl. 339.

reasoning, for the theory of the mental impressions, which was so readily adopted in the barbarous middle ages, as a mode of saving poor and innocent women from torture and stake, finds even in the present day more advocates than might have been expected. Of this I was convinced at the Congress of Naturalists at Aix-la-Chapelle in 1847, and in the Report of the Transactions of the *Schweizerischen Naturf. Gesellschaft zu Chur*, 29, 30, 31 Juli, 1844, in which the affected mind of the pregnant woman is said to produce a mysterious effect on the fœtus, and that the medium by which this influence is communicated may be the hearing as well as the sight! To crown all these absurdities, we see mentioned in Rust, *Magasin*, B. xxi. S. 261., that a woman gave birth to a child with imperfect bones, which is attributed to her having been present, *before her pregnancy*, at the execution of a criminal by breaking on the wheel. To all these fantastical considerations I oppose the following arguments: —

a. That malformations seldom, or perhaps never, agree with apprehensions or fears *à priori* of pregnant women (G. Vrolik, T. Zimmer, J. J. Plenck, and Burdach). On the contrary, it often happens that a woman who has once procreated a malformation, and is continually troubled by the fear of another similar sad occurrence, may become the happy mother of a second well-formed child.

b. That the fœtus, even when a germ, is quite independent; transferred from the ovary into the uterus, it needs for its developement a material intercourse with the maternal body, but no *organic* connection; for which reason it can be formed as well without as within the uterus, as in extra-uterine pregnancy; that it stands in no connection, either vascular or nervous, with the body of the mother, and that therefore it is improbable that her mental condition can have any influence whatever upon the form of the fœtus.

c. That malformations occur likewise among the inferior animals,—insects, testaceous animals, echinodermata,—in which the developement of psychical life is very imperfect, and the oviparous generation of which must preserve the young from the influence of disordered maternal imagination.

d. That in the case of twins, as the acephali specially show, one child may be malformed and the other in perfect condition, notwithstanding they were both exposed to the same influences.

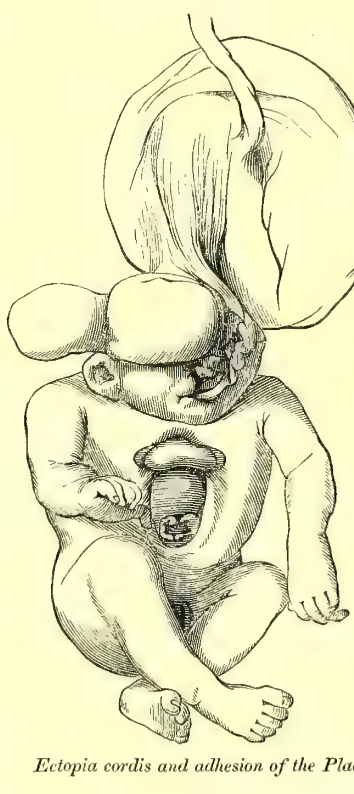
e. That more deeply situated organs, the very existence of which may be unknown to the pregnant woman, may be malformed; as for instance, the heart, the intestinal tube, &c.

If now, on all these grounds, I exclude the mental impressions of pregnant women from the ætiology of malformations, I do not mean to deny the influence which by her somatic condition the mother may exercise upon the fœtus. Thus, if in consequence of mental agitation, her body were to suffer a violent shock, this might have a prejudicial influence on the material transmission which takes place between her and the fœtus, and the latter might thereby become morbidly affected. There are instances of its being the subject of intermittent fever (P. Russell); of sudden death occasioned by frightful agitation of the mother (Wienholdt); of jaundice communicated by the mother (Kerckring); of small-pox (Jenner, Montgomery, Friedlander); of syphilis and scarlet fever (R. Lee), all derived from the mother. But all this is entirely different from the effect of mental impressions. It is a material result, easily conceived, and of which physiologists need no further explanation.

2. A second cause of malformation of the fœtus is sought in external injury suffered by women during their pregnancy. Meckel goes so far as to reject this entirely. In some deformities, for instance, in *hydrops ventriculorum cerebri*, the effect of external injury is easily proved.

3. A third cause is attributed to diseases of the ovum and of the fœtus. Simpson (Edinburgh Med. and Surg. Journal, No. 127., April, 1836, and Gazette Medicale de Paris, Nov. 1836, p. 393.) has described an acute and chronic form of placentitis, to which ought to be ascribed all those singular exudations which attach themselves to the fœtus as pseudo-membranes. *Fig*. 595. gives a specimen of adhesion of the placenta to the head of a fœtus deformed by *urania*.

Fig. 595.



Ectopia cordis and adhesion of the Placenta.

In *fig*. 596. a pseudo-membrane passes to the forehead, round which is twisted the umbilical cord.

Fig. 596.

In some, but very rare, cases, the coats of the ovum are destroyed, and the fœtus is immediately attached to the inner surface of the uterus (Steinmetz). It is not to be denied, that through these pseudo-membranes some malformations of the fœtus may be occasioned, as Montgomery has proved, such as the truncation of the extremities, which he names *self-amputation*. Further than this, however, we may not go, for the *brides placentaires* of Professor St. Hilaire are certainly not a universal cause of monstrosity. They are too accidental and unstable to be such. The existence of malformations in eggs which Geoffroy St. Hilaire coated over with varnish or wax, affords no proof of the possibility of a mechanical origin of monstrosities. The exclusion of the air prevents, in such a case, the necessary material change in the ovum, in consequence of which the perfect developement of the fœtus is impaired.

The morbid state of the coats of the ovum may likewise cause the so-called *molæ*, which, according to their consistency, are divided into *molæ fungosæ*, *carnosæ*, *cruentæ*, and *tendinosæ*. Valentin* distinguishes in the sanguineous mass of *mola carnosa* a net of vessels, from which the blood issues. It is the vascular net of the chorion, in which the mass of blood has been collected, in consequence of too great a supply from the uterus. By these means the villi are distended and removed. The ovum being thus degenerated, occasions defective respiration and nutrition of the fœtus, which in consequence soon dies. The ovum, however, may still continue to grow, and is finally expelled. In this manner these *molæ* are frequently the cause of miscarriage.

* Repert. Anat. u. Physiol., Berlin, 1837, B. i. S. 127.

Kerckring* inveighed in a spirited and ingenious manner against the strange accounts which were formerly given of these *molæ*.

To the diseases of the placenta are referred *enlargement* (Kyll, Pierrard, Devilliers), *congestion* and *apoplexy* (J. Clarke, Darigan), *calcareous concretions* (Hannover). For the ætiology of malformations, this pathological anatomy of the placenta is, however, very unproductive. None of these can be explained by it, nor were any accompanied by these placental diseases.

Nor does the nosology of the fœtus afford us much more information, notwithstanding the monograph given by J. Gmesser.† It cannot, however, be denied, that some of its diseases may give rise to deformities; for instance, chronic inflammation of the brain to *hydrops ventriculorum cerebri*, and this again to *Acrania*.

Perhaps also, as Rokitansky states, a morbid condition of the valves may be the cause of some congenital abnormities of the heart. Yet, notwithstanding all this, the diseases of the fœtus can only, in a very limited sense, be assigned as the cause of its malformation; and hence the opinion of Otto, who ascribes to this source a great many malformations, ought to be rejected.

4. A fourth, and assuredly very general, cause of malformation, consists in impeded developement of the fœtus by some remote and unknown cause. It is matter of dispute whether this deforming cause operates on the fœtus in its totality, or whether it affects originally only one system, which spreads its deforming influence over all the others. This last idea was embraced by Tiedemann, who at first deduced all monstrosities from some defect of the vascular, and later from the nervous system. In opposition to this hypothesis, I suggest the following considerations.

a. It is opposed to anatomical evidence. The *cyclopia*, whose nature consists in a more or less simplified eye and a displaced or absent external nose, is attributed by Tiedemann to the original absence of olfactory nerves, producing the deformation of the nasal cavity, and the original fusion of the optic nerves, and of the thalami nervorum opticorum effecting the simplification of the eye. I have found, however, in *cyclopes*, more than once, olfactory nerves, and have likewise seen that there was no constant concurrence between the simplified form of the eye and of the optic nerve. A double optic nerve may be found with a single eye-ball (Eller, Henermann). With complete duplication of the internal parts of the eye, and even with two separate eyes, I found a single optic nerve, and likewise a double, though not complete, as well as a single eye-ball, notwithstanding the entire absence of the optic nerve. Similar facts are quoted by Haller and G. F. Wolff. Hare-lip with cleft

* Specil. Anat. Amstelodami, 1670, Observ. 38 et 95.

† Die Krankheiten des Fœtus. Breslau, 1827. 8vo

palate is attributed by Tiedemann to the original absence of olfactory nerves. G. Vrolik found them, however, in children with hare-lip. The nerves of organs may exist, although the organs themselves may be absent (Seiler, W. Vrolik); and inversely, the nerves may be wanting, while the organs are present (C. G. Buttner). In *anencephali* the body is very massive, notwithstanding the imperfect condition of the nervous centres. In double monsters there is no definite correspondence between the condition of the nervous system and the duplication of the body (W. Vrolik).*

b. Embryogenesis teaches that the formation of the several parts of the body is not essentially the result of that of the nervous system, but that, on the contrary, each part is formed and developed independently. I refer to what I have already said, in 1836 (in my treatise on *Cyclopia*), and am happy to find J. Muller, Rathke, Bischoff, Burdach, and Stannius, with me on this subject.

What is now proved for the nervous system, may equally be applied to the system of blood-vessels; and hence I presume to conclude, that no malformation whatever proceeds from a central system, but is occasioned merely by impeded developement, the cause of which remains concealed. This impediment may be confined to one part, or may be extended over more. This extension may sometimes stand either in causal connexion with an original malformation, as for instance the displacing of the nose in *cyclopes*; or may take place in an entirely independent manner. In the latter case, it is a complication of malformation, which proves that it may extend itself to more than one region of the body, and to more than one apparatus. I have met with an instance of this, in which to *acrania*, *cyclopia*, and absence of the lower jaw, was added *ectopia* of the intestines. If the origin of the malformation is derived from impeded developement, the so-called *monstra per defectum* are the result, and from excessive formation arise the *monstra per excessum.*

The malformations occasioned by impeded developement may, for the most part, be compared with the natural forms through which the fœtus passes in its normal developement. On this is founded the ingenious idea of Meckel, previously suggested by Wolff, that most malformations are caused by arrest of developement (*bildungshemmung*), for which reason they must be said, according to Bischoff, to be *formed through arrested developement* (*hemmungsbildungen*). They, however, never give us a perfect representation of the form at which the fœtus has been arrested in its developement, because the increased growth and the progressive nutrition of the fœtus cannot but make an important modification therein. As the transient forms of the human fœtus are for the most part comparable to the persistent forms of the lower animals, the malformations occasioned by impeded developement often acquire a brute appearance; and thus a reason is at the same time given why they exhibit, in different animals, the form of the lower, but not of the higher classes.

A consequence of this mode of origin is, that they never deviate so much from the normal form as would exclude them from the rank of organized beings; and that the deviations from the natural form are confined within definite limits, so that they always reremind us more or less of the regular form. Fixed laws of organization prevail in them, by which they exhibit a certain fitness of organization, and a tendency to render the capacity for life as great as possible, notwithstanding the malformation. Peculiar vital relations are hereby produced adapting them for uterine life, and many are brought forth well nourished and at full time. Most, however, are unfit for life after birth, though for very different reasons.

The following remarks may serve for the elucidation of these peculiar vital accommodations: —

1. We never see in malformed births, dissimilar parts fused or united with each other, such as the intestinal tube with the aorta, the arteries with the nerves, &c. Each part, therefore, retains, to a certain degree, its own independence, according to what Fleischmann denominates *lex proprietatis.* The gullet sometimes coalesces with the larynx, and the bladder with the rectum; but these parts are not originally dissimilar, being developed from a common mass.

2. The malformed parts are restricted to their determinate place, according to what Fleischmann denominates *lex topicorum.*

3. No malformed organ loses entirely its own character, and no malformed animal loses its generic distinction. It is, therefore, justly observed by Sœmmering, that nature does not deviate *ad infinitum*, and that even in monstrosities a distinct gradation and natural order are observable.

An immediate consequence of this must be, that in one and the same sort of monstrosity, there are different degrees of malformation, varying from the greatest possible degree to the very least. We might thus consider the different monstrosities as so many genera, and their varieties as so many species, whereby, according to J. T. Meckel, a new organic kingdom is constituted, differing only from the others by less constancy of form. Consequently a definite type prevails in the generation of monstrosities, and they are subjected to fixed organic laws. This order appears even — 1. *In the number* in which they occur within a certain space of time. In 3000 births in Paris, there occurs about one monster (J. Geoffroy St. Hilaire). 2. *In the sex.* In impeded developement, the malformed children are more frequently female,

* On this subject I have given copious elucidation in the Treatise on Cyclopia in Transactions of the First Class of the Royal Netherland Institute, 1836, vol. v. p. 25.; on Double Monsters, *ibid.* 1840, vol. ix.; and Handbuch, vol. i. 1840.

in some sorts of double monsters, male. 3. *In a definite proportion between the species of the animals, and the most frequent monstrosities in them. Cyclopes*, for instance, especially with a snout, occur most frequently in swine; double monsters in man. 4. *In the constant form of monsters, even amongst the most heterogeneous animals. Cyclopia*, double monsters, *acrania*, have in Birds precisely the same characters as in the Mammalia. 5. *In the greater predisposition to monstrosity among some animals.* This is greater among domestic than among wild animals; greater among the more perfect, than among the less perfect; three-fourths of the monstrosities occur among Mammalia, one-fourth among Birds (J. Geoffroy St. Hilaire). They happen seldom among Reptilia, still less frequently among Fishes, Mollusca, Articulata, and Radiata.

From these premises the consequence is easily derived, that monstrosities do not take place by chance, and therefore do not by any means deserve the so very general appellation of caprices of nature (*lusus naturæ*). The result of this is, that they often present a quantitative antithesis, according to what Geoffroy St. Hilaire denominates *loi de balancement.* According to this law, the excessive developement of one part of the body is often connected with checked formation of another. To *anencephalia*, *cyclopia*, *spina bifida*, are often joined fingers and toes in excessive number; to *sireno-melia* superfluous vertebræ and ribs; and frequently there occur in double monsters malformations of the head. Meckel saw, in one single instance, this antithesis extend itself over different children of one and the same mother. A girl had on each extremity a superfluous digit, and one hand of her sister wanted four fingers, being the number of digits which her sister had in excess, reckoning the four extremities together.

I have now arrived to the classification of monstrosities; but in order to prevent all unnecessary waste of time, I shall avoid entering into a full critical examination of the systems propounded by Licetus, Huber, Wigtel, Malacarne, Buffon, Blumenbach, Breschet, Geoffroy St. Hilaire, Gurlt, Otto, and Bischoff. Concerning these I refer to Bischoff*, from whom Rokitansky has chiefly borrowed what he gives in his manual. According to my conviction, no suitable classification of monstrosities can be given, and the efforts employed to this end may be regarded as failures. I confine myself, therefore, to a simple *grouping*, taking embryogenesis as my basis, without presuming on any further classification, and I thus avoid a barbarous nomenclature, which, in my opinion, is attended with no advantage. My object is simply to make the doctrine of malformations useful for physiology and for medical practice, nearly in the same manner as was done, almost simultaneously with me, by the excellent F. A. von Ammon.*

* Entwickelungs Geschichte mit besondere Berücksichtigung der Missbildungen, in R. Wagner Handwörterbuch d. Physiologie, B. i. S. 887.

Malformations of the Ovum.

1. *Mola botryoides* or *hydatica*, — *Hydrometra aquatica*,—is a degeneration of the chorion into vesicles of different sizes, filled with a serous liquor, which were erroneously taken for hydatids. They cover the surface of the enlarged ovum, and are the villi of the chorion, which, as no formation of vessels took place, retained their original vesicular form (Ruysch, Albinus, Sandifort, Cruveilhier, Velpeau). Sometimes a fœtus is found in it, which, however, in relation to the ovum may be said to be small.

The small embryo most probably dies in the early period of pregnancy, and the degenerated ovum continues to grow till a later period, when it is evacuated. In most cases abortion is the consequence of this condition of the ovum. Sometimes, nevertheless, the pregnancy lasts till the full time (Gregorini), or sometimes longer, as happened in a case observed by Lossius, in which it lasted six years. Sometimes the fœtus disappears, and then this degenerated vesicular mass is evacuated alone, with excessive hæmorrhage and great pain. This is the last period of what is called *false pregnancy.*

The vesicles are inclosed in a kind of decidua; they are fixed on pedicles, from which arise other vesicles with smaller stems, so as to give to the whole the appearance of the chorion, in an earlier period of its existence, when the villi still preserve their original vesicular form. The accurate observations of Boeck show that, in most cases, these vesicles contain blood, which sometimes can be displaced by pressure from the one to the other vesicle, or is coagulated. The internal surface of the membrane which forms the vesicle is smooth, the external interwoven with fibres. A thus degenerated ovum has not the power of bringing the fœtus to a state of perfect maturity. The death of the fœtus and miscarriage are its consequences. Sometimes the *Mola botryoides* is accompanied by malformation of the fœtus (Valisnieri).

From this degeneration ought to be distinguished: 1st. The vesicular degeneration of the placenta, when retained after a natural parturition in the womb (Gregorini); 2nd. The *Polypi fugaces* or *vesiculares* evacuated in the anni climacterici by elderly women (Levret); 3rd. Those after suppressed menstruation in unpregnant women (Schleierbach, Watson, Sporing, Lisfranc). As I have no observations of my own of any of these cases, I dare not pronounce any opinion about the affinity of these vesicles to the *Mola botryoides.*

2. *Separation of the placenta into lobes or cotyledons.* — This is without doubt to be attributed to an arrest at a lower degree of developement, and it offers some resemblance

* Die angeborenen Chirurgischen Krankheiten des Menschen. Berlin, 1842.

to the placenta of the Ruminants. The smallest amount of deviation is a division into two coherent lobes, which are separated only by a small constriction (J. F. Meckel, Ebert). Such a placenta has an oblong form. Sometimes there is a single lobe adjoined to the placenta (*placenta succenturiata*); it is of much smaller dimensions than the placenta itself, and united to it by vessels, without a cord. The placenta may also be divided into three (Rohault, Schwencke), four (Hoboken), five (Meckel), or seven lobes (Kerckring, Wrisberg). In the observation of Kerckring, the arrest at a lower stage of development is clearly shown by the presence of the *Vena omphalo-mesenterica*.

3. *The vessels of the umbilical cord are separated* near the placenta, and meet at a considerable distance from it (Sandifort, Wrisberg, Adolph). In one of the published cases, this disposition of the vessels was the cause of their rupture, which produced the child's death by hæmorrhage. Sometimes they were observed to run separately from the placenta to the abdomen of the fœtus, into which they penetrated through separate openings. In most cases they meet each other just at the umbilicus (Gavel, Van Solingen).

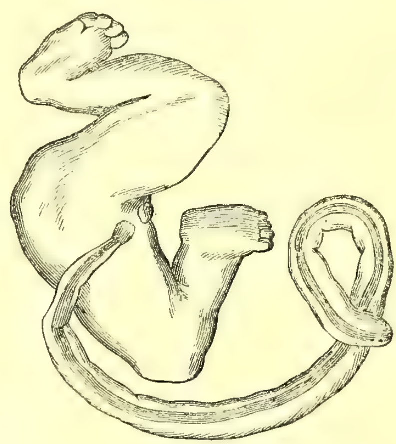
Fig. 597.

Malformed Fœtus, showing the cord entwined around the neck and part of the body.

4. *The umbilical cord too long.*—The common length of the cord is twenty inches (Roederer, Wrisberg), but it may be forty-eight inches (Wrisberg), sometimes even five feet (Morlanne). The usual effect of such an abnormal length of the cord is a circumvolution of it round the body of the fœtus. An example of it is given in a very misformed fœtus in *fig.* 597.

A circumvolution of this kind may sometimes become dangerous: 1. By acting as a ligature round the neck, and producing strangulation of the fœtus (Buchanan, Hebenstreit); 2. By constricting one of the extremities, and producing the *spontaneous amputation* of Montgomery (Art. Fœtus, *fig.* 157. Vol. II.) 3. By forming single or compound knots. Although these are in general not dangerous, while the vessels are sufficiently protected against pressure by the Whartonian gelatine, they may nevertheless in some cases be drawn so tight as to obstruct the communication between mother and child (Sandifort, Irvets, D. W. H. Busch); and sometimes the umbilical cord breaks off near the knot when the vessels have become obliterated by the pressure. *Fig.* 598. gives an example of this in an acephalus.

Fig. 598.



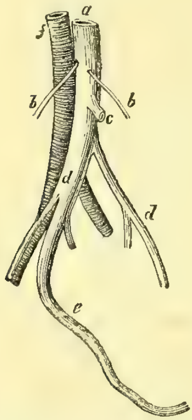
(*After Bonn.*)

5. *The umbilical cord too short.*—Wrisberg gives as a minimum a measure of seven inches. It may, however, be much less. This shortness of the cord is in general accompanied by a deformity of the fœtus, usually by *ectopia* of the abdominal viscera, by which it indicates an arrest of developement at an earlier period of embryogenesis. In this way we should interpret the accounts of absence of the umbilical cord.

6. *Absence of one of the umbilical arteries*, is even observed in double monsters, but occurs principally in *ectopia viscerum abdomi-*

nalium, and in defective formation of the inferior part of the body. Serres hence derived the conclusion, that this malformation is the consequence of the want of one of the umbilical arteries; which is however wrong, as the evolution of the whole body may be complete, even when one of the umbilical arteries is wanting. *Fig.* 599. represents a specimen of this kind.

Fig. 599.



a, aorta; *b*, *b*, spermatic arteries; *c*, superior mesenteric; *d*, *d*, common iliacs; *e*, the single umbilical artery; *f*, vena cava.

Mende even observed in a very well formed child absence of one of the umbilical arteries, together with an unusual course of the umbilical vein, which, instead of communicating with the vena portæ, opened immediately into the right auricle of the heart.

7. *Increased number of the vessels of the cord.* — A double umbilical vein is constantly to be found in the Quadrumana of the New World (Rudolphi). In Man the unusual plurality of the umbilical vessels is but apparent, as it is produced by the persistence of the *vasa omphalo-mesenterica.*

8. *Persistence of the umbilical vesicle*, is a natural condition in the *Ouistiti* (Rudolphi), and occurs as a deviation in Man. Sometimes it is only its duct that remains united with the small intestine, forming what we call a *diverticulum.*

9. *Constriction of the umbilical cord* occurs at the point where the cord penetrates into the abdomen. In the constricted part the vessels, although remarkably narrowed, still allow in some measure the circulation of the blood. The cord is thereby contorted into a spiral. The death of the fœtus is its usual effect (Landsberger). *Fig.* 147. of the second volume of this Cyclopædia gives a representation of this constriction of the umbilical cord.

10. *The umbilical cord too thick.* — Its diameter varies from $1\frac{1}{2}$—$2\frac{1}{2}$ inches. This is, in general, the consequence of an uncommon accumulation of the Whartonian gelatine, or of an œdematous conditon. In one of the recorded cases, the superior extremities were wanting, and the anus was closed. In other cases it is occasioned by an enormous quantity of the liquor amnii, which is usually accompanied with an abnormal developement or impeded growth of the fœtus.

Malformations of the Fœtus.

It is impossible to give in a concise article, such as is suited to a cyclopædia, a complete description of all the various malformations of the fœtus. I must refer to my manual, published in Dutch, under the title *De menschelyke Vrucht beschouwd in hare regelmatige en onregelmatige ontwikkeling*, Amsterdam, 1840 en 1842, and to my *Tabulæ ad illustrandam Embryo-genesin Hominis et Mammalium*, where a more full and accurate description of the various kinds of malformations of the fœtus is to be found. I can give here only a short description of the principal groups, as an introduction to the doctrine of the malformations of the fœtus.

A. Monstrosities produced by an Arrest of Developement.

I. *Non-closure of the anterior Part of the Body.*

Embryogenesis teaches us, that the thoracic and abdominal cavities are originally open, and close themselves by degrees at a later period of uterine life. The late ossification of the sternum and of the pubic bones is the result of this original disposition. The points of ossification are not formed in the broad cartilaginous basis of the sternum before the fourth or fifth month of pregnancy; they are in the beginning widely separated from each other by broad intervals in the middle, and approach later to fuse into one central osseous piece. This mode of formation explains some of the original malformations of the sternum; namely, its abnormal breadth, the openings which are found in it, and its separation into two parts. These two last conditions denote, that the sternum is the compound of two lateral halves fused together (Rathke). The separation of the sternum into two parts usually accompanies *ectopia* of the thoracic and abdominal viscera.

Sometimes, although the thoracic viscera are enclosed in their cavity, the original division of the sternum remains, and is covered up by the skin (Ficker, Serres, Winslow). In some rare cases, the whole or the largest part of the sternum is absent in individuals with no other deformity (Von Ammon). In most of these cases the manubrium alone is present (Wiedemann). In some, but very rare, cases the anterior wall of the thoracic and abdominal cavity is only closed by the skin, and its osseous and fleshy parts are completely deficient (R. G. Mayne). The linea alba is, as well as the sternum, the cicatrix of a cleft existing at an earlier period. This explains its abnormal breadth, obvious in those cases in which the wall of the abdomen has been closed at a later period than usual. An example of it is given in my Tabula XXIV. *fig.* 4. Sometimes the muscles of the anterior abdominal wall are wanting, in which case the convolutions of the intestines may be seen and felt through the skin (Von Ammon). The thoracic and abdominal cavities being open in the first periods of embryogenesis, if this condition persists abnormally, it produces *ectopia of the thoracic and abdominal viscera.* The aperture through which the *ectopia* takes place has a constant tendency to close; it shrinks therefore sometimes to a very small opening (Hammer). Sometimes it is closed in the middle, by a band which separates the uncovered viscera into two portions (Hühner, Wolff).

Its principal forms are: —

1. *Fissure of the whole anterior Wall of the Body.*

a. Complete ectopia of the thoracic and abdominal viscera, which lie bare upon the anterior surface of the body, to which is generally added a cloaca. (*Fig.* 600.)

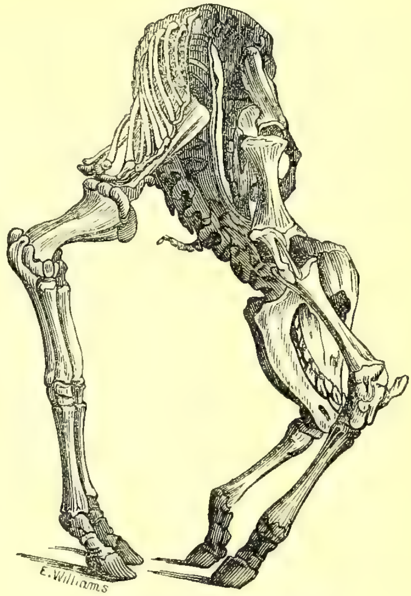
Fig. 600.

Child with ectopia viscerum.

a, liver; *b*, heart; *c*, *c*, lung; *d*, stomach; *e*, spleen; *f*, *f*, intestinal canal; *g*, kidney; *h*, chorion; *i*, amnion; *k*, umbilical cord; *m*, placenta.

The skeleton is very imperfect, in this complete ectopia; the thorax open, and the vertebral column misformed by *scoliosis.* — This may produce, as often met with in calves, a complete inversion of the body, so that through distortion of the spine, the head is placed between the hind feet. This is what Gurlt calls *schistozomus reflexus*, and what I represent in *fig.* 601.

Fig. 601.



Schistozomus reflexus (Gurlt).

2. *Fissure of the Thorax.*

Ectopia of the heart. — In the regular evolution of the fœtus, the opening on the anterior wall of the body closes itself, first at its superior part, so as to cover the thoracic viscera, while a part of the abdominal intestines still remain out of their cavity and in the sheath of the umbilical cord. Thus the thoracic cavity is in general already closed, whilst the abdominal is yet open. Nevertheless, it sometimes happens that the abdominal cavity is completed, and that its viscera are perfectly enclosed, whilst the thorax remains open, and the heart is placed on its anterior surface. In this malformation, called *ectopia cordis*, the heart has no pericardium, and is situated on the median line of the anterior wall of the thorax; it is more or less rounded, and in general well formed, as may be seen in *fig.* 595. The sternum is wanting (Tournelle, Norand, Sandifort); divided into two parts (Buttner, Martinez); or formed only by the manubrium (Manchardt). It is rarely complete; but this is often the case when the heart protrudes at the neck (Muse, Bubonnais, Breschet), or in the epigastric region (Wilson).

During fœtal life, the ectopia of the heart is immaterial, but soon after birth it causes the death of the child. Cruveilhier published some interesting observations on the movements of the heart in a case in which life was protracted for a longer time than usual.*

* British and Foreign Review, No. XXVI. October, 1841, p. 533.

3. *Fissure of the anterior abdominal Wall.*

a. Complete ectopia of the abdominal viscera.—The abdominal cavity is in general the last closed. When it alone remains open, the abdominal viscera only lie out of the body. The fissure is mostly extended from the ensiform process of the sternum to the pubic bones. One of the umbilical arteries is in general wanting. Commonly this malformation is complicated with adhesion of the membranes of the ovum or of the placenta to the divided integuments of the abdomen, with a cloaca, with defective generative or uropoietic organs, and with an incomplete pubic articulation.

b. Congenital umbilical hernia. — In a less degree of deformity, the fissure is limited to the epigastric region, above the insertion of the umbilical cord, because this part of the abdomen remains longest open. This gives origin to *congenital umbilical hernia.* — The umbilical cord passes under the viscera, which lie exposed, or are only covered by the peritoneum. In the last case a sort of hernial sac is formed, which has a cylindrical or globular form, and is produced by the two coats of the ovum.

The external coat is that part of the amnion which is the covering of the umbilical cord; the internal, the peritoneum, which is considered by Meckel as a continuation of the chorion from the umbilical cord. All these facts prove that *congenital umbilical hernia* is caused by an arrest of developement at that stage, in which a part of the abdominal viscera are contained in the sheath of the umbilical cord. The size of the tumor is variously modified by the number and by the volume of the viscera contained in it. When it contains the liver, it is of a bluish colour. The viscera lying in it, are always in an imperfect condition. Only four cases are known, in which the life of the malformed child lasted for any time after birth (Meckel, Cruveilhier, Ribke, Van der Voort); in the case of Van der Voort for eight, in that of Ribke for twelve months. In all these cases the external coat of the hernial sac has mortified, and the tumor has become gradually covered by the skin. An accurate diagnosis of this malformation is of great value. In two cases, in which it was not accurately recognised, a ligature was put round the tumor, and it was cut off. One of these cases was the subject of an interesting law proceeding.

c. Congenital ventral hernia. — The abdominal cavity may also remain open, below the umbilical cord (Fried, Hasenest, Bouchard). This produces congenital ventral hernia. The viscera lie exposed, or are covered by the peritoneum.

d. Acquired umbilical hernia. — Hernia in the umbilical cicatrix ought to be distinguished from all these forms of *ectopia.* It is not a congenital deformity, but is produced after birth by an expansion of the umbilical cicatrix to a globular, a cylindrical, or a conical tumor. It is often observed in adults. If we adopt for these the name of acquired, and for those of new-born children that of congenital hernia, it would be better to give to the true congenital umbilical hernia the name of *hernia funiculi umbilicalis* (Seiler).

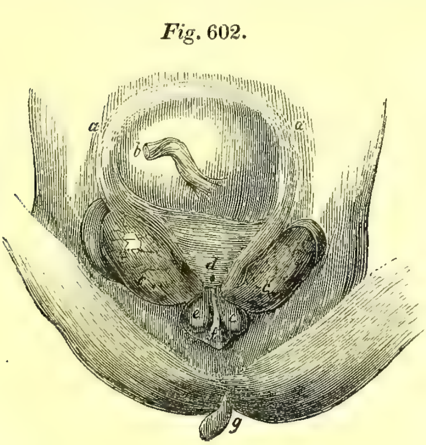
4. *Fissure of the pubic and hypogastric Regions.*

It sometimes happens that the pubic region alone remains open. For a correct idea of the malformations produced by it, it should be borne in mind that in the Mammalia, and, as recent observations teach, also in Man (Bischoff, Wagner, A. Thompson, Coste, Sevres, Arnold), the urinary bladder is formed by the allantois. This is originally in communication with the inferior part of the intestinal canal, so as to form for both a common outlet, called a cloaca, from which are evolved at a later period the peripheral openings of the intestinal tube, and of the uropoietic and generative organs. The pubic bones are formed later than the iliac (Meckel) and the previously existing ischiatic bones. Their formation proceeds from the outside to the inside; therefore they are at first separated from each other by a large interval, and subsequently approach each other, in a gradual manner, for the formation of an amphiarthrosis. The fœtus may be arrested at this period of incomplete pubic articulation. In an observation of Walter, there was a fissure in the pubic region, though the genital and uropoietic organs were not malformed. This is the normal condition of some mammalia, and of the majority of birds. An arrest of developement may also take place at the period when there exists a fusion between the rectum and the allantois. Of this various forms occur.

a. Formation of a cloaca.— A *cloaca* is said to exist, when the generative and urinary organs and the rectum have a common outlet. This is often complicated with *ectopia* of the thoracic and abdominal viscera. The cloaca may also exist alone. In its highest degree, the ureters, the imperfect organs of generation, and the opening of the rectum, are situated close to each other in a circular depression (Petit). In other cases, which approach more to the natural condition, there is a primordial urinary bladder, formed of two separate parts (Mery), or merely constituted by its bare posterior wall. *Fig.* 602. shows how the fissured urinary bladder may be complicated with the formation of a cloaca.

In most of the cases which I have published, the opening through which the fæces are evacuated, is formed by the ileum, and the rectum is closed or wanting. This confirms the original formation of the intestinal tube by a *mouth-* and *anus-gut.* In a case mentioned by Jung these two portions are quite separate, and have each its separate opening on the prolapsed posterior wall of the urinary bladder. When these two openings are fused, the cloaca persists, but approaches more to the natural condition. This may take place in different ways:— 1. The orifices of the ureters only may be found on the posterior wall of the bladder, or in the so-called inverted bladder, while the rectum still coheres with the genital organs, just as in the cases of imperforate anus just mentioned (Meckel, Burns), or with an open anus, as in the cases of Zhryham, Oliver, and Bonnet; this condition approaches the nearest to the natural state,

Fig. 602.



Hypogastric region of a Child, which lived twenty-two days, with vesica inversa, &c.

a, a, congenital umbilical hernia; *b,* umbilical cord; *c, c,* the separated halves of the vesica urinaria, with the urethral orifices; *d,* anus; *e, e,* penis epispadiacus; *f,* frenulum; *g,* cutaneous appendage to the closed anus.

if the urinary bladder is complete (Martin); 2. The rectum may be separate, while the urinary bladder remains fissured and fused with the genital organs (Meckel, Gross); 3. The fissured urinary bladder may be separated from the anus, without taking up the ureters, which then open themselves into the rectum (Meckel, Oberteuffer). In some cases the outlets of these three apparatus are found not on a flat surface, but in a cavity. The cloaca, existing previously on the surface of the body, is then removed from it and folded in, so as to form a cavity.

In another degree of malformation the cavity is formed, and the uropoietic and generative organs are completely separated from each other; but the rectum, being a distinct organ, is nevertheless in connection with one of the said parts, by means of a sort of canal. In the female sex this communication is found between the rectum and vagina (*fistula ani vaginalis congenita*); in the male sex between the rectum and urinary bladder (*fistula ani vesicalis congenita*). The transition towards the natural state is nearest when the rectum opens into the urethra; to this condition, when it is complicated with an imperforate anus, Papendorp has given the name of *atresia ani urethralis.*

b. Congenital fissure of the urinary bladder.— Without a cloaca, and with a perforate anus, the interior surface of the posterior part of the bladder may lie exposed on the hypogastric region (*prolapsus, inversio, fissio vesicæ*). It then forms a red, spongy tumor, situated somewhat above the separated pubic bones, and involving the umbilicus, so as to give the appearance of a deficiency of the umbilical cicatrix. In male children the orifices of the vasa deferentia are to be found on the inferior part of the tumor. The urethral orifices are papillary eminences on the naked internal surface of the bladder. The urine drops continually out of them, but may sometimes be seen to issue in a small stream. The pubic bones are widely apart, sometimes with an interspace of four inches. They have no intermediate cartilage, but are merely united together by a ligament, without forming a synchondrosis. The consequence of this is a very peculiar reeling in the walk of the malformed subject, and a great disposition to inguinal hernia, due to the absence of sufficient support at the interior surface of the body. The penis is fissured on its superior surface (*epispadias*). The testes are, even in adults, very small, and often retained in the abdomen or in the inguinal canals. The seminal vesicles, the prostate and the vasa deferentia, offer various deviations. In the female sex the labia majora and minora are separated and without a commissure at their upper part. The vagina is often closed or very narrow. The anus is more protruded than in the natural condition.

Sometimes the penis is epispadiac, with a well-formed urinary bladder. In such a case, Bonn found, nevertheless, the pubic bones apart, but united by a ligamentous texture. Although the continual dropping of the urine is a very annoying disturbance, which I contrived to remove by the means illustrated in *figs.* 603 and 604, and although the generative organs are very incomplete, this malformation is not dangerous to life, which in several cases has been remarkably protracted.

Fig. 603.

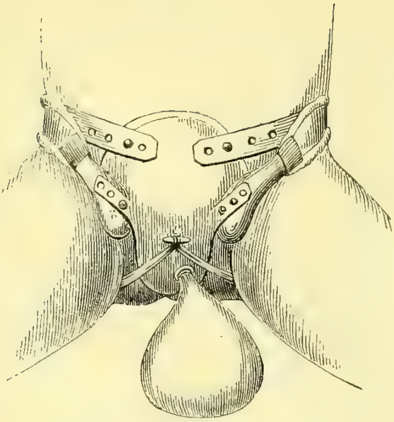
Fig. 604.



The same Region armed with an Apparatus for the reception and evacuation of Urine.

c. Ectopia vesicæ urinariæ. — The smallest degree of deformity is when the urinary bladder remains intact, but lies in an opening in the wall of the hypogastric region. It is *ectopia vesicæ urinariæ*, of which a representation is given in *fig.* 605.; and for more details I refer to my "Tabulæ ad illustrandum embryogenesin," etc., Tab. xxx.

Fig. 605.

d. Inversio vesicæ uninariæ. Prolapsus vesicæ urinariæ inversæ.—If the urachus remains open after birth, the urinary bladder may be expelled, and thereby inverted through it. R. Froriep (*Chirurg. Kupfertafeln*, Heft 67. Taf. cccxl.) has given an example of this malformation. It ought to be distinguished from the inversion of the bladder through the urethra, which is possible even in adult women (Voigtel).

If we take a general survey of all these cases of non-closure of the hypogastric region, it is evident that they are intimately connected with one another.

The cloacal disposition is the highest, the *ectopia* of the urinary bladder the lowest, degree of malformation, and therefore the latter is a distinct transition towards the natural condition. The inversion of the urinary bladder observed by Froriep has, as to its origin, no direct relation to the other forms. It is but an accidental effect of the remaining open of the urachus, through which the bladder chanced to become inverted, and the urine flowed away through the urethra if the child was held upright. From the gradual transition of one form into the other, I conclude that the origin of this malformation cannot well be attributed to a mechanical cause, as Duncan and Bonn have asserted nearly at the same time. They both consider it the effect of a preternatural accumulation of urine, causing a violent distension, and later a rupture of the bladder, of the urethra, of the hypogastric region, and of the pubic articulation. This theory had already, in the year 1816, a very strong opponent in my father (Verh. d. 1[e] kl. van het Koninkl. Nederl. Instit. D. II. B. 88). His chief arguments against it, to which I add my own, are:

1. That, if the urinary bladder bursts, as may happen in adults, the urine will be evacuated into the abdominal cavity, without fissuring the anterior wall. 2. That it is improbable that in some cases such an accumulation should fissure the whole apparatus, and in others restrict its effect to the corpora cavernosa, penis, and the urethra, as may be seen in simple *epispadias* (W. Vrolik, Bosson, Salsmann, Morgagni, and Oberteuffer). 3. That by an observation of Baillie is proved, that in fissure of the urinary bladder the posterior part of the urethra may remain intact and closed, while the corpora cavernosa are fissured at the anterior part of the penis. 4. That I have often found in the fœtus *atresia urethræ* complicated with an unusual expansion of the urinary bladder and of the ureters, but without the least sign of bursting or of producing the malformation in question. 5. That *ectopia* of the urinary bladder demonstrates that the anterior wall of the abdomen may be open, the urinary bladder remaining intact; or the supposed effect may exist, when the cause is absent. From all these and other remarks and observations I conclude that the origin of this malformation is not to be found in a mechanical cause, neither internal nor external (Roose). I am much more inclined to ascribe all its different forms to arrest of developement. My chief grounds for this opinion are the frequent coexistence of:—1. The want of *arteriæ hypogastricæ* (G. Vrolik); 2. Abnormal condition of the kidneys and the ureters (Pinel, Cooper, Isenflamm); 3. Fissured dorsal vertebræ (Littre, Revolat, Delfin, G. Vrolik); and many other malformations, as *labium leporinum* (Dupuytren, Meckel), confluent toes (Saxtorph). The only question which remains is, what is the cause of this imperfect developement? As to the cloacal

formation, it is certain that it may be said to be an arrest at an earlier period of evolution; but this is not certain with regard to the *vesica fissa*. The origin of this can only be explained by an imperfect developement of the urinary bladder from the allantois. It is not improbable, as my drawing of the cloacal formation shows also, that the urinary bladder is formed by two half-parts, which approach each other anteriorly and posteriorly on the mesial line. If this junction does not occur, the different forms of vesica inversa will be formed. *Atresia ani* is, in the cloacal disposition, without doubt, an arrest of developement at an early period of embryogenesis; for previously the anus is closed. And *epispadias* shows that the penis is formed by two parts, which may remain separated from each other on the superior surface. Consequently it appears, that the name of *vesica inversa* is as improper as that of *vesica fissa.* But I shall propose no other name, because we know sufficiently the meaning of it.

5. *Cervical Fissure* (*Fistula colli congenita*).

Recent observations teach us that the original branchial fissures may persist in the neck even in adults. Hyrtl mentioned this malformation in a man of twenty, in whom the external cervical opening was small and communicated with the pharynx close to the epiglottis. Among 34,000 young men, Riecke found a *fistula colli congenita* twice.

6. *Fissure of the Face.*

In order to obtain a correct notion of the different forms under which fissure of the face may occur, it will be necessary to know the gradual metamorphoses of the face during its developement. Originally there is a common oral and nasal cavity. The place of the nose is occupied by two fissures, which extend from the internal angles of the eyes to the superior margin of the oral cavity. There is at this period not the least indication of a palate, so that the mouth and the nose form one common cavity. In a human fœtus of less than an inch in length, Meckel found the first rudiment of a palate, in the form of an arc or a horse-shoe shape. On each side this arc is gradually completed, so as to be at first open at its posterior part, but closed afterwards, and forming a complete transverse plate, separating the nasal from the oral cavity. Rathke examined this more in detail, in fœtuses of the sheep: —

1. He learned that the supermaxillary cavity is formed on each side from the lateral walls of the cranium.

2. That between those two parts grows out of the frontal wall of the skull a third eminence, which forms the basis for the septum of the nose, that is, for the formation of the vomer, of the septum of the ethmoid bone, and of the intermaxillary bones.

3. That the two parts, quoted under No. 1., are bent inwards, and coalesce with the mesial part.

4. That the nasal cavity is at first a groove, and has originally a form which persists through their whole life in fishes.

5. That the oral and the nasal cavity form originally a common cavity.

6. That the palate is originally a fissure. By arrest of developement in these different stages of embryogenesis, are formed the different species of facial fissure.

a. *Complete fissure of the face.* — The highest degree of malformation is, when the fissure is extended from the angle of the mouth to the internal angle of the eye, the orbits, the nose, and the mouth forming but one cavity. J. S. Meckel, Van Doeveren, and myself have published examples of this malformation complicated with *acrania*. The fissure sometimes extends only over one lateral part of the face (Leuckart), and in the greatest transition to the natural condition it is but a shallow groove, as is represented in *fig.* 596.

A fissure sometimes extends in a transverse direction over the head. C. Meyer observed this twice in new-born sheep. In both the palate had a double fissure, and the normal opening of the mouth reached as far as the ear, which in one of these lambs presented a transverse fissure.

b. *Double labium leporinum.* — A transition to the normal condition, yet a very imperfect one, is when the fissure is not extended over the whole surface of the face, but is restricted to the upper jaw. The highest degree of deformity is *double hare-lip with fissured palate* (*Labium leporinum duplex cum palato fisso*). On each side of the upper lip a fissure extends from the angles of the mouth to the *alæ nasi.* Between these is a protuberant tubercle, covered by a separate part of the upper lip, and consequently by the external skin and the gums. The tubercle is connected with the septum of the nose, generally obliquely distorted, and is filled up with the germs of the incisors. By the confusion of the oral and nasal cavities, the true nasal orifices are wanting, the osseous palate is defective, the soft palate and the uvula are fissured, and the vomer united anteriorly with the protuberance, hangs in the midst of the fissure. In a lesser degree of malformation, the alveolar margin of the upper jaw is alone fissured, and in the least degree the palate is complete.

c. *Single hare-lip.* — This name is adopted for the malformation when it is limited to one lateral part of the face. It may be complicated with fissured palate. The lip is then, on one side, fissured to the nostril, so as to form there an immediate communication between the oral and nasal cavity. The direction of the fissure is seldom accurately in the mesial line. If this occurs, it is the result of defective intermaxillary bones. The palate offers either a simple or a double fissure. In a less degree of malformation only the alveolar ridge is cleft, and, in the least, the palate is complete. In such a case the fissure of the upper lip is merely a small incision.

d. *Fissure of the palate without a hare-lip.* — The alveolar margin is in this case quite complete, but the palatine and the supermaxillary bones are largely separated from each other posteriorly, so as to form a fissure, more or less extensive, of the bony and of the soft palate. Sometimes there is only a fissure of the uvula (Von Ammon). The nearest approach to the natural state is, when the planes of the palatine bones form with each other an acute angle rising high upwards in the nasal cavity (Himly, W. Vrolik). In some cases, the palate is fissured at its anterior part, close to the *foramen palatinum anticum* (*hiatus foraminis palatini antici*, Von Ammon). *En resumé*, it appears that fissure of the palate and hare-lip are independent of each other. But it may happen that, originally, the fissure of the palate coexists with the hare-lip and closes itself later. The indentation which is observed in hare-lip without fissure of the palate, between the external incisive and the canine tooth, makes it probable that nature proceeds in this manner. It is also not improbable that hare-lip may sometimes be cured spontaneously in the womb. The gradual transition of the various forms of this malformation into each other, shows that its cause is not external and accidental, and that it is produced, neither by blows which the child inflicts upon itself with its fists (Jourdain), nor by a mechanical impediment preventing the union of the palatine laminæ (Pinnder). Complete fissure of the face and the palate is rather to be considered as an arrest of developement at an early period of formation. Hare-lip conforms with the fœtal condition in that period of developement which I have called the third. If the original intermediate protuberance does not unite itself with the lateral parts, double hare-lip is formed. The protuberance obvious in it is formed by the intermaxillary bone either in its totality, or only by a part of it. If it unites itself with only one lateral part, single hare-lip is formed. The intermaxillary bone is composed of four separate parts, of which each contains an alveolus. The result of this is, that each of these parts may be united, separately, with the supermaxillary bones ; which fact explains clearly why only three or two incisive teeth are sometimes to be found in the protuberance. The fissure of the upper lip sometimes occupies the mesial line, passing through the middle of the intermaxillary bone. This is also the case when the intermaxillary bone is wanting.

In this way, all the various forms of fissure of the face can be reduced to an arrest of developement, which explains in the meantime the constant tendency of the fissure to close itself, as may be observed in children having this malformation. Fissure of the palate and lip does not endanger the life of children, and union of the separated parts in hare-lip and cleft palate can be obtained by a surgical operation.

e. *Fissure of the under lip.* — The under lip is very seldom cleft (J. F. Meckel, Von Ammon, Nicati, Bonisson). It is equally rare for the under jaw to remain after birth separated into two parts.

II. *Fissure of the Skull* (*Acrania*).

Many forms of this monstrosity are known, to which different names have been given, as *acephalia spuria*, *microcephalia*, *anencephalia*, *hemicephalia*. But, for its shortness and etymological sense, I prefer the name of *acrania*, which was introduced by J. F. Meckel. Under this name I comprehend all the different forms in which this malformation occurs, and also, with Himly, the *hernia cerebri*. According to my opinion, the division into different families and genera, and the nomenclature of J. Geoffroy St. Hilaire, ought to be rejected. I, for my part, am always inclined to simplify science as much as possible, and to be succinct in its exposition; and I propose, therefore, the following types.

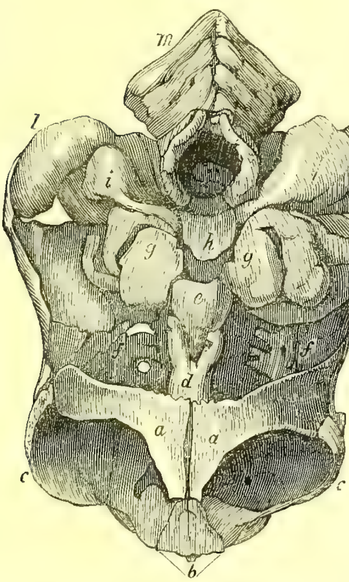
First Type. — *Want of the brain, and exposure of the whole basis of the skull.* — The superior surface of the cranium is flat, and not formed by the bones of the skull, but only by a membrane, of which the margin is very unequal, hard, and formed by bones. The external integuments extend over this margin, and terminate there in an unequal line, which is distinctly circumscribed by the thick hair of the head. With this cutaneous border is connected the slightly vaulted membrane, of a red, somewhat bloody colour, which immediately covers the periosteum that invests the more or less convex surface of the basis of the skull. The brain is wanting, but the central terminations of the cerebral nerves are in most cases present, yet sometimes these also are wanting (J. F. Meckel). The forehead is flat, and directed forwards in an oblique direction. The eyes protrude on its anterior or orbital margin, covered with swollen superior eyelids, and directed more or less upwards. The face is flat, and nearly horizontal ; the upper, and still more so the under jaw are comparatively longer than those of a well-formed subject ; the tongue is in general prominent, because the mouth cannot be shut on account of the

Fig. 606.

length of the under jaw. These distortions give to such monstrosities a certain brute-like aspect which induced the Germans to call them *Katzenkopfe* and the French *têtes de crapaud*. If the cervical part of the spinal column is in the meantime cleft, the cervix is so shortened, that the head seems to be fixed on the shoulders, and the chin rests on the breast, as is represented in *fig.* 606.

The malformation of the bones of the skull and of the face is very great; but as its description would take too much room here, I refer the reader to my *handbook* and my plates, and also to *fig.* 607., which will give a clear idea of it.

Fig. 607.



Skull of a new born Child with Acrania.

a, a, frontals; *b,* nasals; *c, c,* very convex zygomatic bones; *d,* small ensiform processes; *e,* sella turcica; *f, f,* alæ majores ossis sphenoidei; *g, g,* petrous bones; *h,* basal part of the sphenoid bone; *i, i,* condyloid parts of the occipital bone; *l, l,* depressed squamous parts of the occipital bone; *m,* small osseous laminæ, representing the parietal bones.

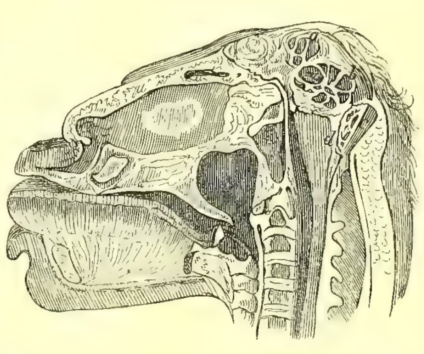
Second Type. — *The denuded surface of the basis cranii occupied by a spongy substance, instead of brain.* — In most cases vesicles, filled with a serous liquor, were observed to occur in this spongy substance, and with these occasionally also medullary corpuscles, which may be considered as rudiments of brain. There is sometimes a rudiment of the cerebellum, together with a rudiment which is continued into the spinal medulla, as though it were a medulla oblongata. The cerebral nerves are sometimes quite separated from, sometimes united with, the spongy substance. Sometimes they have the form of complete or lacerated bags, which extend along the superior surface of the skull and the posterior surface of the spinal column. The spinal column is either perfect, or partially, and sometimes entirely, cleft. The last of these conditions is represented in *fig.* 608.

Fig. 608.

To this form of monstrosity Geoffroy St. Hilaire gives the name of *anencephalus*. Specimens of it were found amongst the Egyptian mummies in the sacred sepulchres of the *Cynocephali* and *Ibis*, which is a very interesting fact as regards monstrous births in those times.

Third Type. — *The surface of the basis cranii only partially denuded, — a spongy tumour occupying the place of the brain.* The skull may be closed at its posterior part, and remain open at its summit. A more or less malformed cerebral substance appears on the summit of the skull, just as if it were

Fig. 609.



Section of the Head of a Child with Acrania, to show the union of the malformed brain with the spinal cord.

a, b, cellular sacs, taking the place of the brain; *c,* occipital bone; *d,* spinal cord.

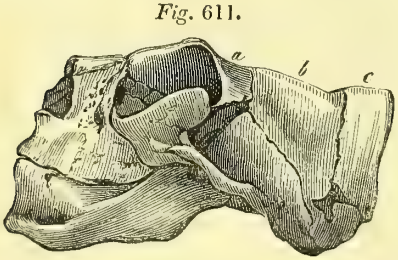
a hernia. The parietal bones are sometimes present, together with flat frontal bones, and a perpendicular occipital bone, so that the summit of the skull is quite closed, with the exception of a small opening. *Fig.* 609. shows how the malformed cerebral substance is applied to the medulla spinalis. All the cerebral nerves are present.

This form of monstrosity has in general a less brute-like aspect; the trunk is more evolved, and the whole body in general very heavy.

Fourth Type.—*The skull flat, more evolved, but having an opening, through which the brain protrudes as a hernia.*—This is what we call a cerebral hernia (*hernia cerebri, encephalocele*), viz. a tumour covered with the external integuments arising from some part of the surface of the skull, and containing a part of the brain. It has commonly the form of a bag, appended to the posterior part of the skull, and resting on the neck. The head is never turned with the face upwards; the ears do not rest on the shoulders; the neck is not wanting. The summit of the skull is flat and closed, and its cavity is too small to include the brain, which for this reason is placed on its outside, and backwards. The occipital bone has the form of a vertebral arc, which surrounds the brain, lying at the outside. *Fig.* 610. shows the external appearance of this monstrosity, *fig.* 611. the structure of the skull.

Fig. 610.

Fig. 611.



a, frontal; *b*, parietal; *c*, occipital, bones.

In many of the published observations, a collection of serous fluid accompanied the *hernia cerebri*, by which a *hydro-encephalocele* was formed.

The situation of the cerebral hernia is in general on the occiput, but sometimes on both sides of the root of the nose (W. Lyon, Kelch); above the eye (Adams); on the forehead (Beclard, Saxtorph, Niemeyen, Bredon, Guyenot); on the fontanella magna (Held); in the parietal bone (Le Dran, Stein, Tren); on the glabella, between the orbits (Otto).

On a survey of these various types, it appears that they all belong to the same class of monstrosities. The nature of the malformation is in all the same, namely a defective developement of the skull and of the brain. This takes place in different degrees, so as to convey us gradually from the complete want of brain to those cases in which it is nearly perfect, and differing from the natural condition only in situation. The constancy of form is very interesting in this monstrosity, so that the malformed children resemble each other nearly in every museum, and the published observations are quite accordant with the cases now occasionally occurring. This proves that the origin of the malformation cannot be accidental. The want of the neck, which is the reason why the ears rest on the shoulders and the chin on the breast, and which gives to this form of monstrosity such a peculiar character, is often the consequence of the want of some of the cervical vertebræ (Rathke, Haller, Otto), or of their mutual coalition (Rathke, W. Vrolik), or of their shortness (Sandifort.) As a transition to the brute form, this shortness of the neck is interesting, reminding us of the condition of the Cetacea. The prominence of the eyes is occasioned by the flatness of the orbits, and by the backward direction of their superior margin. It differs from the manner in which the eyes are prominent in children with internal hydrocephalus. A rich growth of hair is common to all the forms of *acrania*. Is not this, and likewise the abundance of areolar tissue, to be attributed to a vicarious nutritive function? The frequent absence of the suprarenal glands (Otto), or at least their imperfection and smallness (Morgagni, Hewson, F. Meckel, Soemmering, W. Vrolik) in all acranial fœtuses is remarkable. The capacity for persistent life after birth differs according to the different forms of this monstrosity. Acrania does not seem to interfere with uterine life. The children who are affected with it are all well nourished, and some of them even very large, at the moment of their birth. Nevertheless, they rarely live longer than a few hours. During this short life they offer some symptoms which are attributable to the reflex action of the nervous system; such as, for instance, muscular contractions when the skin is touched, rejection by the mouth of the recently expressed juice of *Pelargonium tomentosum*, and the attempt to suck a finger introduced into the mouth. In cerebral hernia the chance for the prolongation of life is greater. Some cases are known in which life lasted 20, 30, and even 60 years. When complicated with hydrocephalus, puncture has sometimes been instituted, but without success (Earle). Extirpation produced, in another case, instantaneous death.

What are the causes of *acrania?* From some of its forms, it is clear that there has been hydrocephalus followed by disruption (Morgagni, Penada, Sandifort, Klein, Otto). In an embryo figured by M. Schroeder Van der Kolk, the summit of the head is extended by hydrocephalus, and has on its superior surface a black gangrenous spot which seems to prognosticate a rupture.

In another fœtus I observed a fissure in the midst of an analogous spot. According to my opinion, the lacerated bags, which are sometimes found on or in the summit of the naked internal surface of the basis cranii, or at the back part of the more developed skull, are caused by such ruptures. Tiedemann gives a description of such a bag, filled with serous fluid, but not yet burst, and situated upon the head of a fœtus, which has the external appearance of *acrania.* (*Fig.* 612.)

Fig. 612.

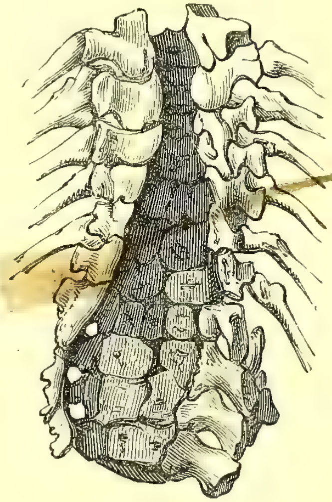
But in those cases in which the flat basis of the skull is only covered with a membrane and with cerebral nerves, in those in which there is a spongy substance upon it, and in those in which the skull, although flat, is otherwise complete, not the least probability exists of the rupture of a cerebral vesicle at an early period of formation. I am able to prove this, I think, by a small fœtus of two months, in which the superior part of the skull is wanting, and in which a spongy mass occupies the place of the brain.

It shows that *acrania* may also be a primitive malformation, occasioned by the simultaneous malformation of the brain and of the skull. Why I do not impute these malformations to external injury, such as the leaping of a monkey on the belly of a pregnant woman (Sandifort), to a fall down stairs (Pauli), or to the influence of imagination, needs not be demonstrated.

III. *Fissure of the Back Part of the Body.*

Hydrorachis and *Spina bifida.* — Fissure of the spinal column (*spina bifida*), and dropsy of the spinal medulla, occur each separately, or connected together. In the highest degree of fissure, the vertebral bodies even are cleft (J. T. Meckel, Tulp, Fleischmann). *Fig.* 613. represents such a case, after Cruveilhier.

Fig. 613.



In a less degree, the vertebral bodies are complete, but their arcs very defective, being completely wanting, or laterally incurved and fused together. In the lowest degree, the two halves of the vertebral arcs are completed, but not united together, so that posteriorly an open space remains between them, and a fissure occupies the place of the *processus spinosi,* which are separated into two lateral and equally incurved parts.

When this form of fissure of the spinal column is not accompanied by *hydrorachis,* both parts of the vertebral arcs are not bent laterally, but meet each other so exactly, that no open space remains between them. Sometimes the fissure is extended over the whole vertebral column (*spina bifida totalis*), sometimes it is but partially cleft (*spina bifida partialis*). The partial fissure occurs more frequently in the lumbar than in the cervical region of the column. The cause of the greater frequency of the partial fissure in the lumbar region is to be imputed to the termination of the spinal medulla in this region; to its expansion there under the form of cauda equina; to the larger sheath formed there by the dura mater; and to the very limited tendency which the osseous nuclei of the lumbar and sacral vertebræ show to unite themselves into an arc, which therefore remains always open at the inferior part of the sacrum. Although it occurs sometimes alone, this sort of fissure is generally accompanied with dropsy of the spinal medulla (*hydrorachis*), that is to say, with a sac of a reddish-violet colour, in which fluctuation is easily discerned. Its external covering is sometimes formed by the skin, and then it has the usual colour of the body; the skin, however, does not in most cases cover the whole surface of the tumour, but ceases at its circumference, and the rest of its surface is only covered with the dura mater. When the child lives, the dura mater becomes, after some time, thicker, harder, and more solid. When the tumour is covered with the skin, the dura mater is to be found under it. These membranes become often so thick, and so intimately united together, that it is nearly impossible to separate them from each other. The serum contained in the tumour is of a very variable quality, principally composed of albumen, mucus, gelatin, and muriate of soda (Bostock). It is effused between the pia mater and the arachnoidea, or between this and the dura mater, or in the primitive canal of the spinal medulla. If this canal remains open, the *hydrorachis* is in general accompanied with *hydrocephalus internus*. Sometimes these sacs are found on more than one spot of the spinal medulla, or divided into two by a septum. The size of the sac varies, and the complication with hydrocephalus is very dangerous. If this is the case, the artificial opening of the sac has a very injurious effect. Convulsions and exudative inflammation are in most of the cases excited by it. In some very rare cases the operation was attended with success. Sir Astley Cooper healed *hydrorachis* by reiterated puncturing with a thin needle and by compression of the tumour. Dubourg is said to have treated it with success by means of excision of the tumour and bringing together the lips of the wound with needles, in the same manner as in the operation for hare-lip. Beynard tied a ligature round the sac. E. de Thinecourt compressed the tumour, after having opened it, with two small rods, which he connected and pulled together by means of ribbons. The noxious effects of *hydrorachis* after the child's birth make it necessary to try an operation. Before birth this malformation seems not to have the least influence upon the health of the child: it is well nourished and duly constituted. After birth the noxious effect is modified by the different seat of the tumour. When seated in the lumbar and sacral region, it is the least dangerous. It is known that some individuals have lived with it twenty-eight years. In most cases, however, paralysis of the inferior part of the body is its consequence. *Hydrorachis* in the cervical region is much more dangerous. One case of this is mentioned in my "Tabulæ," in which death suddenly occurred on opening the tumour.

Besides *hydrorachis*, some other malformations of the spinal medulla are observed sometimes to accompany fissure of the spinal column: 1. Complete want of the spinal medulla, commonly connected with *acrania*; 2. Its appearance under a cylindrical form, with persistance of the primitive medullary canal (Morgagni, Santorini), which is sometimes double (Gall, Von Ammon); 3. Fissure of the spinal medulla into two juxtaposed cords; so that it seems to be double, which is occasioned by an arrest of developement at that period of its evolution in which the two halves, of which it is formed, are as yet separate; 4. The presence of a simple nervous expansion instead of spinal medulla; 5. The lamellar form of the medulla; 6. A too great length.

By all this it is proved, that fissure of the spinal column may be accompanied with *hydrorachis*, and with an imperfect developement of the medulla. They are totally independent of each other, and each is produced by its own cause. It is, however, not very improbable that a voluminous sac on the medulla may prevent the union of the points of ossification, by which the vertebral arcs are to be formed; but we are not, I think, justified in concluding from this that *hydrorachis* is the cause of the fissure of the vertebral column. For it may exist without fissure of the spinal column, if it has not acquired the form of a bag; and the spinal column may be cleft although the spinal medulla is intact. This leads me to the conclusion, that malformation of the spinal medulla, *hydrorachis*, and fissured spinal column, do not essentially go together.

IV. *Hydrocephalus congenitus.*

Congenital dropsy of the brain.—Under this name we understand such a great volume of the head in a full-grown fœtus that it opposes in general a mechanical impediment to parturition, which can only be removed by an artificial diminution of the volume of the head. Its forms are — 1. *Hydrocephalus internus;* 2. *Hydrocephalus externus.*

1. *Hydrocephalus internus* is said to exist when the abnormal serous secretion occurs in the ventricles of the brain, wherefore it has also acquired the very rational name of *hydrops ventriculorum cerebri.* It may be an altogether primitive malformation, when the brain is arrested at that period of its developement in which it has the form of a very thin vesicle, filled with a serous fluid. I have observed this condition principally in Cyclopes, and give an example of it in *fig.* 614.

In such case there is no indication of the hemispheres, nor of the convolutions of the brain, and, in general, no difference to be seen between the white and the grey cerebral substance. In small fœtuses of two months, in which the bones of the skull could not yet be discerned, this form of hydrocephalus has

Fig. 614.

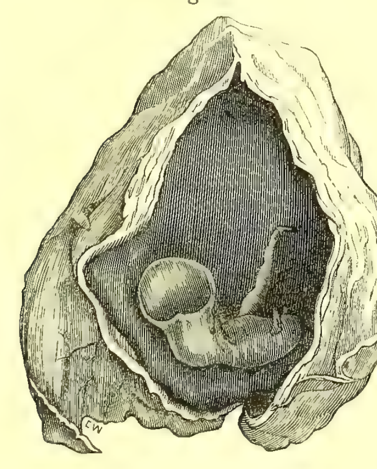
a, a, medullary expansion filled with serous fluid; *b,* optic nerve; *c, c,* peduncles of the brain; *d,* pons varolii; *e,* medulla oblongata; *f, f,* cerebellum; *g,* spinal medulla; 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, the cerebral nerves, existing besides the optic nerve.

been observed (G. Vrolik, Rudolphi). See *fig.* 615.

Fig. 615.



(*Altered from Rudolphi by W. Vrolik.*)

Human Ovum, with an Embryo of two months, affected with hydrocephalus.

Internal hydrocephalus is, however, not always occasioned by arrest of developement in an early period of formation, but may be produced by chronic inflammation, (G. Vrolik), to which the child is, without doubt, as much subject during uterine life as after its birth. The principal causes of it seem to be external injuries suffered by the pregnant woman, and sometimes even reiterated contact by the act of copulation, if the pelvis is large, and the womb seated very low. Pseudo-membranes are on this account often found on the internal surface of the expanded ventricles (G. Vrolik), by which the deposition of the serous liquor may be limited to one or more of the cerebral ventricles, so as to produce an a-symmetrical expansion of the head; this is, on the contrary, symmetrical, if both the lateral with the third and fourth ventricle are equally and universally extended by the fluid. The head acquires, in such case, an enormous, but symmetrical, volume (E. Sandifort, W. Vrolik). The slower such a secretion of fluid takes place, the slower the head increases in volume, and the less it endangers life, and the less the free evolution of the mental faculties is interfered with. Some cases are mentioned, in which life lasted sixty years (G. Vrolik), thirty years (Michaelis), and fifty-four years (Gall). It is remarkable that in many of these cases, neither the senses nor the intellectual faculties were in the least impaired. This proves that the substance of the brain is not altered by it, and that the form only of the brain is changed by the unfolding of its convolutions. This unfolding is the consequence of the pressure which the fluid exercises from the inside towards the outside, and of the thereby augmented volume of the ventricles (Hunauld, Gall). Those who presume that through the influence of the serum exudated in the ventricles the dissolution and even the total destruction of the cerebral substance may be effected, go evidently too far (Cruveilhier). However large may be the surface into which the hemispheres of the brain have been unfolded, the white medullary substance can always be distinguished from the grey (G. Vrolik). The parts contained in the ventricles are sometimes intact (G. Vrolik), but sometimes incompletely developed, and what we should call depressed (Aurivillius, Büttner, Malacarne, Klein). The corpus callosum assumes a thin lamellar form; the septum pellucidum and the fornix become thinner; the glandula pituitaria and pinealis deviate in general from their natural condition (Friend, Malacarne, Wrisberg). The cerebral nerves are in general not changed, and the cerebellum is in most cases natural. The lumen of the cerebral arteries is commonly very large (Büttner), and Friend saw two internal carotids passing through the carotid canal of the right side. In a few cases there was observed a degeneration of the cerebral substance, which resulted in a deranged and feeble state of the mental faculties (Büttner).

Internal hydrocephalus has always a prejudicial influence upon the condition of the rest of the body, principally upon its nutrition and upon the osseous system, which it predisposes to emollition. It has a very great influence on the bones of the skull. Its effects are: —

a. A large expansion of the skull, whilst the face preserves its common shape, and is in great disproportion to the enormous circumference of the skull. This disproportion is the most significant symptom of hydrocephalus, and distinguishes it from simple amplification of the head.

b. A protuberance of the frontal tuberosities, which is to be considered as an arrest at an early period of developement, occasioning an enormous augmentation of the facial angle, which greatly exceeds a right angle.

c. A pushing downwards of the orbital parts of the frontal bone, which makes the superior orbital margins to disappear totally, and to form a protuberance with the frontal part of the frontal bone. The eyes thence acquire a strange direction, their axes being turned upwards.

d. A-symmetry of the hydrocephalous head, which is always more or less oblique. This is the effect of the unequal expansion of the brain. To this may also be ascribed the strange form which the skull acquires when it is regularly extended and developed on its fore and lateral parts, whilst the occiput has a very singular prominence. Such a form is, without doubt, occasioned by a regular expansion of both the hemispheres of the brain up- and sidewards, whilst their posterior lobes and the cerebellum have preserved their regular form. The parietal bones are thereby expanded and augmented in circumference, whilst the occipital bone, not participating in the expansion, is disproportioned to the rest of the skull. The parietal bones are removed from it, so that, during the primitive ossification, an interval is formed, which is afterwards filled up with Wormian ossicles.

Not less singular is the form of the head and skull, when, probably on account of the position of the head in the womb (as is the case in a *partus pedibus prævüs*), the pressure of the fluid has been exercised principally downwards, so as to extend chiefly the lateral parts of the head.

e. An abnormal disposition of the cranial bones. The fontanellæ acquire, in the first instance, a very large dimension, and some parts of the cranial bones remain cartilaginous, which parts are, in a more advanced period, filled up with Wormian ossicles. Baillie asserts, that sometimes the already formed sutures are opened by the serum exuded in hydrocephalus internus. In other cases, the want of closure of the sutures is to be imputed to a too great thinness of the bones.

2. *Hydrocephalus externus* is by some (Monro, Wrisberg, Hartell) erroneously considered as the result of *hydrocephalus internus*, followed by laceration of the cerebral hemispheres. It is proved, by a great many observations, that such a laceration occurs very seldom. The fluid is, in most cases of hydrocephalus externus, exuded on the surface of the brain. This may be the consequence of an arrest of developement, as I observed in a cyclopic lamb, but it may also be produced by inflammation. The serum is accumulated between the dura mater and the skull, or between the two layers of the arachnoid membrane, but in most cases its situation is between the dura mater and the arachnoid membrane. In all these cases the brain is strongly compressed, shrunken, and hard (Kaltschmidt). Dullness and somnolence are, according to Frank, the consequences of hydrocephalus externus, and convulsive affections those of hydrocephalus internus.

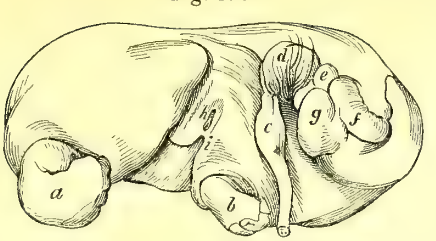
V. *Acephali, or Fœtus without a Head.*

When we observe the fœtus in its first periods of developement, the head is not yet clearly distinct from the trunk. From the third to the fifth week of gestation, the head, not previously discernible, grows so rapidly, that it has in the fourth week acquired the same volume as the trunk. Now the developement of the fœtus is sometimes arrested at that early stage when the head is not yet distinguishable; the result of such an arrest must manifestly be an *acephalus.* This denomination is, again, as erroneous as many others; for not only the head, but many other parts, are wanting. The question remains whether a more appropriate name could be given. Gurlt tried to do so, but, I fear, not with good success. He calls the lowest form of acephali *amorphus globosus,* which is a true *contradictio in adjecto.* I think it therefore proper to preserve the old name of *acephali,* to which I refer, as has been done by Tiedemann and G. Vrolik, nine types, for which I think it not necessary to give special names.

First Type. — *Acephali in the form of a rounded mass, without any indication of extremities.* — Examples have been given by G. Vrolik, Bland, and W. Vrolik, all of twins. The rounded mass is covered with the skin; it contains an intestinal fold, and receives the insertion of the umbilical cord. In general there is found in it the rudimental indication of vertebræ and of spinal medulla.

Second Type. — *Acephali in the form of a rounded mass, with indication of feet.* — The chief observations of this form have been given by G. Vrolik and Clarke, in cases of twins. They have an umbilical cord, rudimental external genital parts, and an anal orifice, with an imperfect abdominal cavity, in which are contained an intestinal loop formed by a colon and cæcum, and kidneys. Consequently all the thoracic viscera, the liver, the spleen, pancreas, stomach, and the small intestines, are wanting; but there is a rudiment of a nervous system, a tolerably complete right inferior extremity, a pelvis, and a left separate foot, without femur and crus. (*Figs.* 616, 617.)

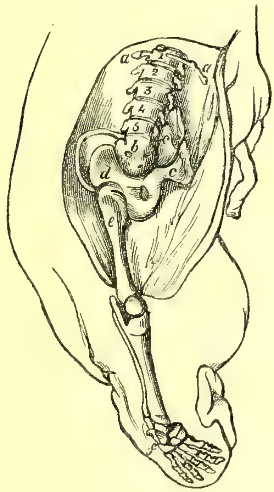
Fig. 616.



Human Acephalus, born along with a well-formed child.

a, the right foot with five; *b*, the left, with three toes; *h*, the female genitals; *i*, the anus; *c*, tumor formed by the umbilical cord; *d, e, f, g*, eminences covered by the skin.

Fig. 617.



The same Acephalus with dissection of the skeleton.

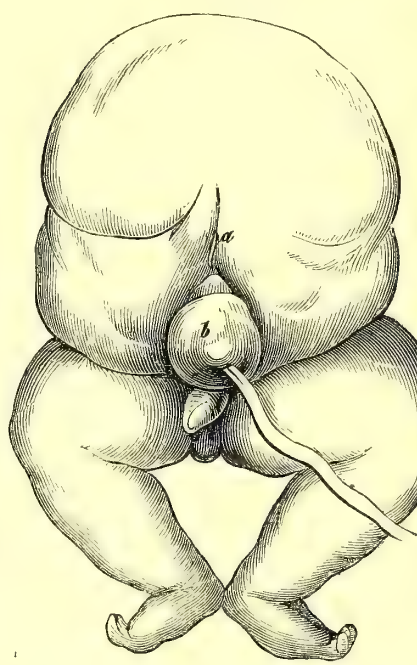
a, a, the only obvious inferior dorsal vertebra, with a pair of ribs; 1, 2, 3, 4, 5, lumbar vertebræ; b, sacrum; *c, c, d*, iliac bones; *e*, femur; *f*, bones of the foot.

Third Type.—*Acephali in which the trunk is more developed, without a head and thoracic or superior extremities, but composed of an incomplete trunk, with an imperfect inferior extremity.* — In the lowest grade of this monstrosity may be ranked an acephalus observed by Ruysch, consisting only of a leg. Somewhat more perfect is the acephalous inferior extremity of a goat, mentioned by Hayn. It consisted of a pelvic bone, with the other bones of the inferior extremity, some muscles, the vessels and nerves of the femur, which were probably connected with the umbilical cord of the perfect goat born at the same time as the acephalus.

Fourth Type. — *Acephali in which the trunk is more developed, without a thorax and without superior limbs, and composed of an abdomen, genital organs, and two inferior limbs.* — The hypogastrium and the two inferior limbs are, then, more or less completely formed parts. With exception of one, all the observations which we know of it are of twins, and in one case of three children born at one birth. In many it is proved that the mother of the acephalus has been often fecundated. They are rarely full-grown at birth, and they have in most instances a placenta common to them and the well-formed child, but with a separate cord; the fœtal membranes also appear to be common to both. The cord of the acephalus contains sometimes two, sometimes three or four vessels (T. H. Kalck). The integuments of the monster, truncated at its upper part, are irregularly tumified, by a large quantity of thick, pale, or yellowish subcutaneous cellular tissue. Interiorly there are lumbar vertebræ, with a pelvis, and the bones and muscles of inferior limbs, besides the spinal marrow and its nerves; the lumbar and sacral parts of the sympathetic nerve; blood-vessels without a heart, of which the arteries are connected with the umbilical arteries, and the veins with the umbilical vein; a loop of intestines; uropoietic, and genital parts. All the other parts are wanting.

Fifth Type. —*Acephali in which the trunk is much more developed, with an imperfect thorax, composed of some dorsal vertebræ and ribs. The superior limbs are wanting.* — The only difference between this and the preceding type is in the more complete trunk, there being a thorax superadded to the abdomen. In all the other points the structure resembles that of the fourth type; they are

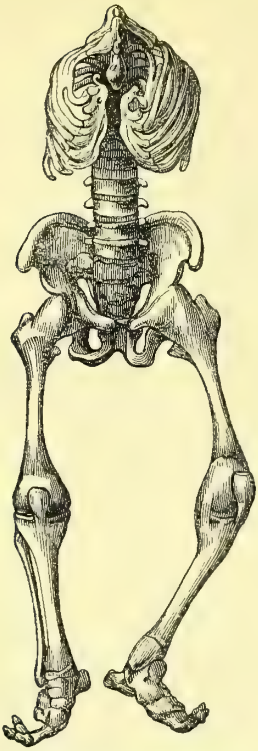
Fig. 618.



Human Acephalus born along with a well-formed child.

a, cutaneous fissure in the lower part of the thorax; *b*, umbilical hernia, under which are the male external genital parts.

Fig. 619.



The skeleton of the foregoing Acephalus.
a, mobile bone connected with the single cervical vertebra.

always twins, and not full grown. As far as it has been mentioned by different observers, there is either a common placenta, with two cords (Ponjol), or with one cord split into two (Mery); or there are two placentæ connected together (Herholdt); or there are two totally separate ova, with a double placenta (Monro). The external appearance differs from that of the fourth type, by greater length, and less truncated upper part of the body, in which a feeble indication of head may sometimes be visible (Ponjol, Prochaska). The integuments are as in the fourth type; the toes are generally malformed; the arms and the external genital organs are often abnormal. To the lumbar part of the spinal column is joined an imperfect osseous thorax, sometimes with cervical vertebræ (Hevermann), but without thoracic viscera. The diaphragm exists in most cases. There are vessels without a heart, which cohere with the umbilical vessels. The viscera of the epigastric region are commonly wanting; Atkinson mentions only a liver. In some intestines can be recognised either as *intestina tenuia* or *crassa*. The uropoietic organs, and the internal parts of generation are commonly present. There is in all a spinal marrow. The observations as to the nervous system are very incomplete. (See *figs*. 618, 619.)

Sixth Type. — *Acephali with a trunk composed of a thorax and an abdomen, and with two superior and two inferior limbs.* — When the trunk is more developed, the thorax becomes more convex, is more distinct from the abdomen, and supports two superior limbs. These acephali, too, are twins, at least in the greater number of the cases. They are often not full-grown, and borne by women who have frequently been pregnant. The placenta is in general common to the two fœtuses, but with two cords. The thorax is more perfect than in the fifth type; the upper part of the body terminates not in an obtuse end, but in a broad and flat surface, having a fissure in the midst, with an indication of a head. The sternum is often rudimentary, and the osseous frame of the superior limbs is very incomplete. To the spinal column are added cervical vertebræ, and sometimes a confused indication of cranial bones. There is usually a diaphragm, but neither heart nor lungs. There are commonly two vascular trunks, an arterial and a venous. With the venous is connected the umbilical vein; and from the internal iliac arteries arise the umbilical arteries. There are uropoietic organs, and an intestinal canal, with a cæcal termination; and sometimes a liver. This latter is, however, sometimes wanting, together with the spleen and the pancreas. In the intestinal tube there is no meconium, but only a mucous substance. The nervous system is very incomplete; but there is constantly a spinal marrow with the abdominal part of the sympathetic. I have observed distinct muscles, of which the presence has been denied by others.

Seventh Type. —*Acephali in which some cranial bones are found.* — This has been observed by Herholdt, in a monster, born twin with a well-formed child, of a mother who had five other children. There was an amorphous head, with an indication of eyes and nose, but without ears and mouth: the rest of the body was much deformed. Of the cranial bones, the condyloid and vertical portions of the occipital only could be distinguished. There was no trace of facial bones. Analogous observations have been made by Curtius and Otto.

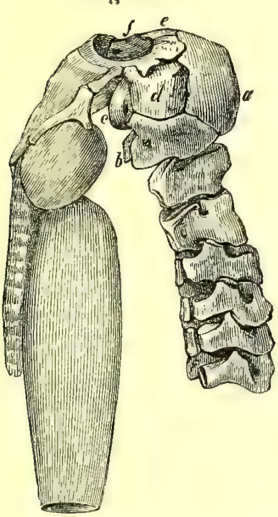
Eighth Type. — *Body and extremities perfectly well developed, and having a neck, which is wanting in the other types. The neck is surmounted and terminated by the ears.* — This is the form to which Gurlt gives the name of *perocephalus aprosopus.* I have met with it in the lower animals only. The body and the limbs are perfectly well developed; on the perfect neck are placed two coalesced ears, behind which there is an imperfect cranium, composed principally of the cranial, *minus* the facial, bones. In all this the deformity makes a transition towards an imperfect formation of the face. (*Figs*. 620, 621.)

Ninth Type. — *Acephali which are composed of the trunk only, without the least indication of superior or inferior limbs.* — Only one case of this monstrosity is known, observed by Vallisneri. In a fœtus of a very mature period of

Fig. 620.

The superior cervical part of a perocephalous lamb, terminated by the ears which are coalesced with each other.

Fig. 621.



The skeleton of the parts represented in fig. 620., *with the trachea and the œsophagus.*

evolution, the head, the superior and the inferior limbs, were wanting. There existed only a trunk, which contained a tolerably large heart, imperfect lungs, a malformed liver, a stomach, and an intestinal canal.

From this survey of the characteristics which distinguish the acephali, we learn that they are born with two, three, or four other fœtuses at one birth. Can this quantitative multiplication of the children be the cause of the qualitative malformation of one of them? This is probable by the great fertility of the mothers of acephali, which also indicates that these monsters are produced by an arrest of developement. It is very easy to reduce their external appearance to the early periods of developement, in which the head is not yet distinct from the trunk, and in which the limbs are not yet protruded. It is worth mentioning that the abdominal cavity, with the kidneys and a part of the intestinal canal, are the most constant organs, which is very interesting with reference to the genesis of the intestinal tract. In the monstrous births of the second, third, and fourth type, there is only a colon, while in those in which a thorax is superadded (as in the fifth and sixth types), there is also an *intestinum tenue* with the cæcum. I regard this as a confirmation of the statement, that the formation of the intestinal canal commences at the two extremes, and proceeds from these to the middle part.

In the same manner the uniformity of circumference of the whole intestinal tube is an arrest of developement at an early period of embryogenesis, to which may also be referred the cæcal beginning, and in many cases even the cæcal termination of the intestine. The frequent deficiency of the liver is the consequence of the absence of the stomach and duodenum, and therefore a sign that the liver is a protrusion of the mucous membrane of the intestinal tube. The connexion between the containing and the contained parts is also very distinctly proved by the acephali. The very general presence of the lumbar part of the spine determines the existence of kidneys; that of the pelvis, the existence of the urinary-bladder and of the genital organs. The very imperfect condition of the thorax is in relation with the absence of the heart. The presence of vessels without a heart demonstrates that the circulation of the blood can be carried on by these alone, and that the formation of vessels is quite independent of that of the heart. The profusion of cellular tissue, by which the swollen appearance of the acephali is produced, may be formative substance, which has not been employed in the production of the other parts of the body, and which has therefore grown rather abundant. In this manner many of the peculiarities of the acephali can be reduced to fixed principles.

VI. *Want and defective Formation of the Trunk** (*Acormia*†).

The highest degree of this kind of monstrosity is where neither trunk nor limbs are formed. Lycosthenes, Rudolphi, and Nicholson describe monstrous births, in which the head is the only part formed.

a. Sometimes only a part of the head is ormed, of which I saw an example in a monstrous fœtus born with a well-formed calf. The tongue was the only well-developed part in it. This shows that in the absence of all the central organs, heart, lungs, skeleton, and brain, there may be a well-constituted skin

* The word *trunk* is here used to include the extremities.

† From ἀ, privativum, and κορμὸς truncus.

surrounding an amorphous mass of cellular tissue, and only a single well-formed organ. I have given a fuller account of this case in my Tab. lxii. *figs.* 4, 5, 6. Therefore we may conclude that each part is formed *sponte suâ*, and that it is in its evolution quite independent of the rest of the body.

b. A less degree of malformation is when the superior part of the body is formed without the inferior limbs. *Fig.* 597. gives a representation of this monstrosity, of which a succinct account is to be found in my Handbook, D. ii. Bl. 100, and Tab. lxiii.

c. In a more perfect developement of the trunk one of the extremities may be wanting.

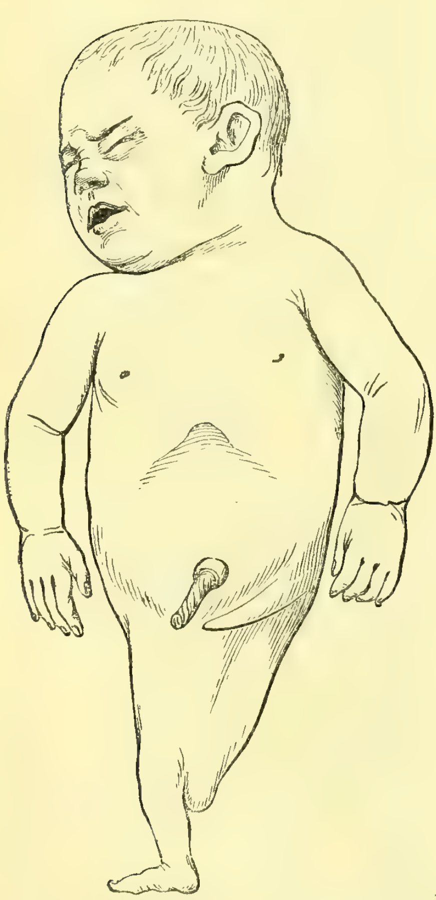
We call this malformation *monopodia;* in it one of the inferior half-parts of the body has not been formed. It makes a transition to those monsters, in which the inferior extremity of the body tapers gradually into a tail-like form, which has given to them the name of *monstra Sireniformia.*

d. *Sympodia* or Siren-like form is the fourth species of defective formation of the trunk. The single inferior extremity is composed of the elements of two, and articulates with a pelvis, which is not formed, as in *monopodia*, by one bone, but by a coalescence of two. In most of them the partially double, partially single inferior extremity terminates in a caudal point; on account of which the name of *Sirenes* has been adopted. To this imperfection are added closed anus, defect of external genital parts, and the existence of but one artery in the umbilical cord. The malformed inferior extremity has not always the same form. Therefore we admit three varieties: — 1. Without a foot, *Sirenomelia* of J. G. St. Hilaire; 2. With a single foot, more or less complete, *Uromelia* of J. G. St. Hilaire; 3. With a double foot. *Fig.* 622. represents the second, and *fig.* 623. the third variety.

Fig. 623.

Sympodia.

Fig. 622.



Uromelia.

By this survey of the four types of defective formation of the trunk is proved that they form a very natural series, in which we are gradually inducted, from the total want of a trunk to monsters in which inversion of the inferior extremities is the only deviation from the natural form. The same regularity is here to be observed as in every other class of monstrosities. It is therefore impossible to ascribe their origin to accidental external causes. Meckel has opposed his own peculiar and sarcastic wit to this absurd ætiology, and gives the very ludicrous account of a surgeon who supposed that the Sireniform monster had been formed during a very difficult delivery. If it is, on the contrary, an original malformation, it may be asked, what can be its remote cause? Is it the original want of one of the umbilical arteries? I should not think so; for one of these arteries is also wanting in the variety in which all the parts of the two extremities are present, and we know that one of them may be wanting in a completely well-formed child. (See p. 948.) Another question is, whether *sympodia* can be attributed to the coalescence of the inferior extremities (Meckel, Kamm, Boerhave, and Cruveilhier). Neither am I inclined to adopt this cause.

1. I cannot imagine a coalesence of bones so complete, that through these could be formed one single extremity.

2. It is impossible to explain by it the imperfect condition of the leg and of the foot in the majority of cases.

3. From such a fusion or coalescence cannot be derived the imperfect state of the rectum, and of the sexual and uropoietic organs.

It seems to me more probable that *sympodia* is due to some original malformation of the pelvis and its viscera, of which the cause remains unknown. The formation of a head solely, of an incomplete trunk without the lower limbs, or of a single inferior extremity, is certainly to be attributed to nothing else but impeded developement. It shows, moreover, that the different parts of the body are quite independent of each other in their original formation.

e. *Original defective formation of the pelvis.* In a well constituted body the pelvis may be originally malformed, as is proved by the *obliquely narrow pelvis* of Nazele, and by the *transversely narrow pelvis* of Robert; of which malformation the cause is to be found in the imperfect formation of the sacrum.

f. *Defective developement of the spinal column.* This has been principally observed in calves. It is too short, defective, more or less incurvated, and some of the vertebræ fused together. The head is situated at a short distance from the thorax; the tail and the anus are reflected to the dorsal surface; the pelvis is too narrow, and turned upwards at its posterior part.

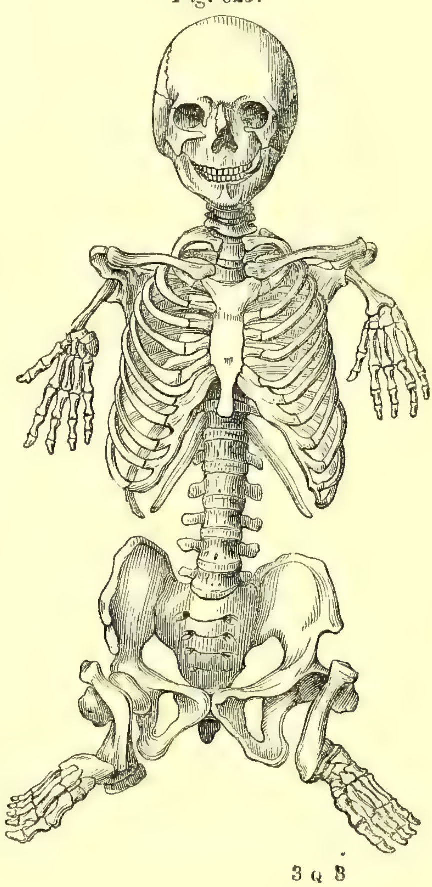
VII. *Defective Formation of the Extremities.*

The origin of many malformations of the limbs may be referred to the early periods of embryogenesis. But for some of them this is impossible.

1. *Want of all the extremities* is an arrest of developement at that period, in which the limbs are not yet formed, and in which small tubercles occupy their places. Sometimes the superior extremities only are wanting, which urges the inferior extremities to acquire a sort of dexterity by which they may in some measure supply the place of the superior limbs. Of all the examples which are known of it, that of Thomas Schweicker is the most memorable. The inferior limbs only are rarely

Fig. 624.

Fig. 625.



wanting, and the cases few in which there is but one superior or inferior extremity.

2. *Want of the intermediate parts in the extremities, so that the hand is attached immediately to the shoulder, and the foot to the hip.* — This may happen in one or in more extremities. Of the last, a very interesting example occurred in the person of a certain Marco Catonze, of whom I represent the external appearance and the skeleton in *figs.* 624, 625., referring for more details to my Tab. lxxvii.

3. *Limbs too short.* — All their parts exist in such case, but are too short, as if they were not full-grown. The malformation is however not limited to the extremities, but extends over the trunk and the head. The head has in all the known cases the aspect of hydrocephalus. The neck is short and broad, the trunk short and swollen, and the limbs short, broad, and thick. Sœmmering and Otto ascribe this to congenital rachitis. But according to my opinion it ought to be attributed to defective developement, which is confirmed by the dissection, performed by C. Mayer, of such a monstrosity.

4. *Limbs which seem to be truncated.*— Sometimes the fore-arm and the leg terminate abruptly like stumps, and present the appearance of cicatrices. I saw this on the four extremities of a calf, of which I have represented the external form and the dissection in my Tabulæ lxxviii. and lxxix. In many of the known cases this defective condition of the limbs seems to be the result of arrested developement. In some others, however, it is the effect of mutilation produced by the constriction of the umbilical cord, or by pseudomembranes. Montgomery has given many examples of it in his article Fœtus in this Cyclopædia. It is an interesting fact that from these stumps may grow rudiments of fingers, as Dr. Simpson showed me during the visit which I paid him at Edinburgh.

5. *Diminished number of fingers and toes.*— The highest degree of this malformation is the existence of but one finger or toe. Sometimes there are only the thumb and the little finger, as may be seen in a preparation in the museum of Ilovius at Amsterdam. The greatest transition towards the natural condition is the presence of four fingers or four toes.

6. *Coalesced fingers and toes.* — In otherwise perfect limbs it is possible that hands and feet may be arrested at that inferior degree of developement, in which they are not yet separated into fingers and toes. The child is then born with fingers or toes, which seem to be coalesced; but that is nothing more than a fallacious appearance. The malformation consists really in absence of fission. Of this there are different degrees: *a*, complete absence of fingers and toes, instead of which there is a common mass; *b*, connection of the fingers and toes by means of a membrane; *c*, the adhesion limited to the posterior parts of the fingers and the toes, while their anterior parts are completely free. All this may be seen in *figs.* 626, 627, 628

Fig. 626.

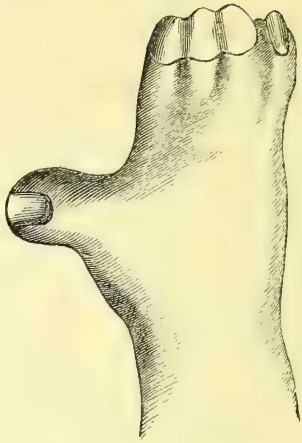


Fig. 627.

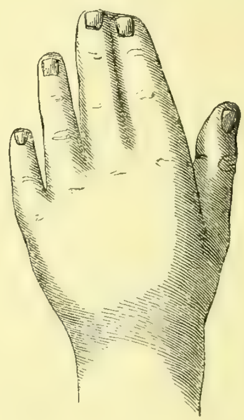

Fig. 628.

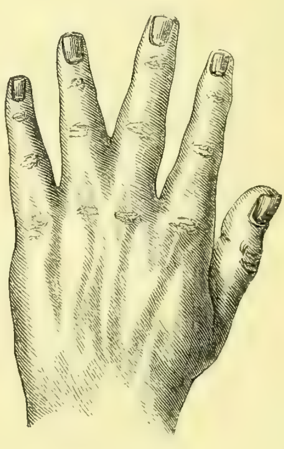

(*After Otto.*)

7. To all these malformations of the limbs ought to be added the abnormal direction of the foot; but this is fully considered in the

article Abnormal Conditions of the Foot in this Cyclopædia.

VIII. *Cyclopia.*

Upon this interesting malformation, which for many years was the object of my own investigations, I should have much to say; but my friend Paget has already given a succinct survey of its different forms in his learned Article Nose, to which, therefore, I refer. I beg leave here to add to the observations which I have published in my former works upon the origin of *Cyclopia*, a few additional remarks on the subject. Is it an arrest of developement? It cannot be denied that many deviations of the parts in Cyclopes may be referred to a previous natural form. For example, in one of my published cases the optic lobe and the brain formed one continuous part, which is certainly an early natural condition. It is also certain that the disposition of the hemispheres of the brain in Cyclopes, which appear to be a single vesicle, accords with the vesicular state of the brain in the first period of its developement, and that the unprotected situation of the ganglia of the brain, of the cerebellum, and of the medulla oblongata, may be considered as a fœtal condition. But, as to the eyes, it is not so certain that their singleness is the result of an arrest of developement. E. Huschke has, however, maintained the opinion, that the eyes are formed by a single vesicle, which becomes separated into two; but from the more recent and accurate investigations of Bischoff, we must conclude that the optic lobes are from the beginning separated and double, taking their origin from the anterior cerebral vesicle, and that from an abnormal condition of this last, by which the rudiments of the eyes approach each other and fuse together, may be derived the cause of *Cyclopia.* If this observation is true, of which it is difficult to retain the least doubt, *Cyclopia* really appertains to the *Verschmelzungs Bildungen* of Meckel in an early period of developement. Perhaps it may be compared with the metamorphosis of the eyes in *Daphnia*, *Cypris*, *Polyphemus*, and *Cyclops*, in which there are originally two vesicular bulbs, which subsequently coalesce into one. But however this may be, it remains certain that the malformation of the cranial and facial bones in Cyclopes is the consequence of the abnormal condition of the brain and of the visual and olfactive apparatus.

IX. *Deficiency of the Underjaw* (*Monotia*).

Want of the under jaw often coexists with *Cyclopia*. By this complication is formed a peculiar series of monsters, which make a gradual transition to those in which, notwithstanding the presence of two eyes, the under jaw is absent. I refer to this the following species.

1. *Total defect of the opening of the mouth,* — as observed by me in a lamb, in which also the ears were removed to the basis of the head and coalesced. The under jaw was totally absent; and behind the coalescent ears there was an osseous vesicular cavity, formed by the bulbous tympanic cavities, united together.

2. *The opening of the mouth represented by a fissure at the inferior surfaee of the face.* — The rest of the external appearance is similar to the first species. The under jaw is wanting, but there is a rudiment of a tongue.

3. *Too short an under jaw.* In man and the lower animals the under jaw is sometimes incompletely developed, and more depressed posteriorly than it ought to be. This original brevity of the under-jaw is the cause of a great many ulterior deformities.

Without doubt, these three forms of monstrosity make a continuous series. They consist, as Bischoff says, in an imperfect developement of the first visceral arc, by which the under jaw and the bones connected therewith are either wanting or defectively formed, the result of which is, that the ears are removed to the basis of the head, and there become fused together. The total defect of the opening of the mouth is the highest, the too short under jaw the least degree of malformation.

Herewith I conclude my brief account of the monstrosities resulting from arrest of developement. The description of the congenital abnormal condition of the different apparatus would oblige me to surpass the due limits of an Article for this Cyclopædia, which already, I fear, may be considered rather too long; and I think this the less necessary, because a great deal of information about them may be found in the Articles Anus, Diaphragm, Fœtus, Hermaphroditism. I therefore pass on to a succinct description of a second group of monstrosities.

B. Monstrosities produced by Excess of Developement.

I. *Fœtus in Fœtu.*

The human fœtus may be included in another fœtus, or adhere to its body. This may happen in two different manners: —

1. *A fœtus more or less perfect contained in the cavity of the body of its twin-brother or sister.*

a. *In the uterus.* — The fœtus would be pregnant in such a case at the moment of its birth. The observations given of it are, however, somewhat apocryphal.

b. *In the abdomen.* — In a case recorded by Fattow, there are, in a fœtus of seven months, two rudiments of fœtuses contained in its abdomen. Such observations are also given by Reiter, Heminger, Pacini, and E. Philips. In general, the rudiments of a second fœtus are very imperfect, and included in a sac. Sometimes, however, they are more complete, which was, for example, the case in an observation of Young, of which the preparation is preserved in the splendid Museum of the London College of Surgeons.

c. *In the anterior mediastinum.* — As in a case recorded by Gordon, in a female of twenty-one years.

d. *In the scrotum and the testes.* — Such cases have been noticed by Rosenberger, Hartmann, D. S. J. Wendt, Velpeau. Sometimes the rudiments of a second fœtus are found in the interior of the testis, sometimes at its exterior surface.

e. *In the stomach.*

f. *In the intestinal canal.* — Highmore has given such a case in a youth of fifteen or sixteen years, in the gut of whom an acephalus was found.

g. *In the orbit.* — According to Barnes.

h. *At the tentorium of the dura mater.*

i. *At the palate.* — It is then in the form of a fungous excrescence, consisting of the rudiments of a second fœtus (Otto, Sandifort, Ehrman, Stadenski).

2. *The more or less developed rudiments of a fœtus adhere, in the form of a tumour, to the external surface of a second body, and are covered by the external integuments.*

a. *To the cheek.* — G. Vrolik observed in a new-born male child, a sac of large circumference, covered by the external skin, and adhering to the region of the left cheek, but without communication with the mouth. In this sac there were tuberculous cartilages, osseous nuclei, and organised parts of indefinite form and composition.

b. *To the neck.* — According to Joube.

c. *To the epigastric and umbilical region.* — As recorded by E. B. Gaither.

d. *To the sacral and perineal region.* — This is the most frequent mode of adhesion, as is proved by a great many observations, among which those of Himly and of Fleischmann deserve special mention. This adhesion takes place in different manners: 1. by external cellular tissue; 2. by internal union with the abdominal and pelvic cavity (Himly, Schaumann, and Stanley); 3. by communication with the spinal canal. There is sometimes no vascular communication between the fœtus and its appendix (W. Vrolik); and in other cases there are large branches going from the *arteria sacra media* of the fœtus to the sac. In general, the sac has its own integuments, over which passes the skin of the fœtus. The genital parts and the anus are always quite separate from the sac, which merely lies in apposition with them. In the majority of the known cases, the rudiments of a fœtus contained in the sac are but confused and ill-determined organic substances, intermingled with a few osseous and cartilaginous nuclei. In one case it was possible to recognise the cranium with the face and the naked encephalous masses (Wedemeyer); Mayer and Blizard found an intestinal loop; Himly saw distinct super-maxillary bones, and rudiments of temporal, frontal, and sphenoid bones, &c.

If we take a survey of all the cases which are designated as *fœtus in fœtu*, it is clear that some may be compared with parasitical diseases formed in the interior of the body of the fœtus. I presume that this is the case, when the mass which is found consists only of hair, fat, teeth, and some osseous nuclei, contained in a cystic tumour. In other cases the rudiments of a fœtus are included with a more or less perfect indication of an ovum in the body of a second fœtus, or adhere externally to it. The large number of theories on the origin of this monstrosity have been criticised by Himly. It is certain that none of them can be maintained. It is most probable that the *fœtus in fœtu* is an incomplete effort to form a double monster. In this sense, some cases of *fœtus in fœtu* make a transition towards that form of double monsters which is named *heteradelph.*

II. *Double Monsters, in which one of the Fœtuses is more or less perfect and the other merely an Appendix to it* (*Heteradelphi*).

Under this name of heteradelphs, which we owe to Geoffroy St. Hilaire, we understand that species of double monsters of which one fœtus is large and perfect, and another, or part of another, adheres to it like a parasite. They should be considered as twins, of which one has been developed at the expense of the other, which other sometimes becomes partially included in its body. According to the more or less perfect state of the appendix, they are reduced to different species.

First Species. — *The appendix consisting of a head only.* — This may be connected: —

1. With the epigastric region (Winslow, Hesse),
2. With the cranium (E. Home),
3. With the back (Chabelard),
4. With the palate (Hofmann), or
5. With the under-jaw of the perfect fœtus (Geoffroy St. Hilaire, G. Sandifort).

Second Species. — *The appendix consists of more or less developed extremities only.* — Supernumerary extremities, more or less developed, are connected with some part of the body of a perfect fœtus, as:

1. Pelvis and two inferior extremities connected with the epigastric region of the perfect fœtus (Serres, E. Sandifort, Trombelli, Mayer, Winslow, Reschel, Buxtorff, Cantwell, Lycosthenes).

The appendix is sometimes more, sometimes less perfect; sometimes connected with the sternum, sometimes with the epigastric region or in communication with them by a cylindrical cutaneous prolongation. In the appendix are regularly formed organs of generation, kidneys, an intestinal loop in communication with the intestinal canal of the supporting fœtus, and vessels which anastomose with those of the latter. The adhering parasite is therefore one with its supporter.

2. Pelvis and the two inferior extremities connected with the lateral wall of the abdomen of the perfect fœtus (W. Vrolik).

3. Pelvis and two inferior extremities con-

nected with the pelvis of the perfect fœtus (Numan, Osiander, Haller).

4. Separate anterior or posterior extremities connected with some part of the perfect fœtus (W. Vrolik, Von Baer).

All these varieties are indicated under the names of *gastromele*, *pygomele*, and *melomele*.

Third Species. — *The appendix is an acephalus with four extremities.* — The union has as yet been observed only at the epigastric region of the supporting fœtus, through which the abdominal cavity was common to the two bodies. In the appendix the genital organs existed, but the anus was closed. In many cases, the evacuation of urine has been observed; the appendix showed circulation of blood; it had its own temperature, and was dependent for nutrition on the chief or perfect body. In the interior were found uropoietic organs, vessels connected with those of the chief body, and an imperfect intestinal canal (Otto, Serres). In the supporting fœtus are sometimes found traces of double organs (Otto, Serres, Rosenstiel).

Fourth Species. — *The appendix a complete body with a head and four extremities* (Bartholinus). — This form of heteradelph makes the transition to *anterior duplicity*. The appendix has but to be more equally proportioned to the chief body, and a completely double monster is formed. The best example of this occurred in the person of a certain Lazarus Colloredo, who lived for some length of time. His portrait is given by Bartholinus.

This very peculiar appendix never took food, nor had it evacuations of fæces. But the organic and the animal life appeared to be very well developed, as its cutaneous exhalation, its movements of different parts of its body, and the fact of its sleeping, showed.

The common character, by which this whole class of heteradelphs is distinguished, consists in the comparatively smaller size, and, in general, the defective developement, of the part which is termed the parasite. Imagine this difference removed by the fuller developement of the parasite, by its obtaining all its own organic apparatus, and by its growing *pari passu* with the other, and an exact idea of complete duplicity will be formed. It will be observed also, that in the several members of this class there is a regularly graduated series, from those in which the superfluous part is only an ill-developed limb, to those in which the parasite differs from the chief in nothing but its inferior size and its dependence for nutrition. The cases of the last kind are, however, rare. I know but three, of which that of the said Lazarus Colloredo, described by Bartholinus, is the most remarkable. Much more commonly the parasite, even when it possesses its full numerical complement of parts, bears many signs of defective developement; it is hare-lipped, or a cyclops, or has *atresia ani*, or some other malformation from arrest of developement. All this seems to me to prove, that in heteradelphs there are always the rudiments of two bodies, though one or both may be defective.

The beings thus formed have rarely lived many years after birth, and the histories of the few that have survived are, for the most part, well known in the records of medicine. Perhaps the most remarkable is that of the Chinese A-ke, of whom and his parasite little models are to be found in most of the anatomical museums of Europe. The parasite's life is, in general, only vegetative. In one of the three cases, indeed, in which it possessed all the constituent parts of a body, it moved its limbs, and appeared to have its own sensations; but in the others, less perfectly formed, even these signs of individual life were absent; and in only one, that of the Chinese A-ke, had the man who bore the parasite any voluntary power over its limbs. The nutrition of the parasite appears to depend entirely on the body to which it is fixed, and through which it both receives its nutritive materials and discharges its excretions. The one increases and decreases in size with the other; and, of course, the parasite dies with the individual to which it is attached. The influence which, in its turn, it exercises on its supporter is not always important. In the heteradelphs that die early, death commonly ensues from the malformation of the main body; if they survive, the parasite seems to do harm only, as an ordinary tumour would, by its weight, and by abstracting a certain amount of nourishment, so that those who, thus burdened, have grown up to childhood or manhood have usually been thin and delicate, like men subject to some unnatural waste. But, nevertheless, it will always be better to tolerate this evil than to risk an operation of removal, when the results of all the examinations yet made prove that the parasite is deeply and by important organs connected with its supporter. The only exception which I know to the correctness of my opinion is the case in which Mr. Blizard removed, with complete success, from the sacrum of a child, a congenital tumour, which seems to have been a *parasite*.

III. *Double Monsters.*

1. *Anterior duplicity.*

It has been already said that some of the rarer kinds of *heteradelphia* approximate closely to the double monsters. In all the cases that stand nearest to the transition, the parasite has been found adherent to the epigastric region; and the kind of duplicity which is most closely related to them, is therefore that in which the two bodies adhere by their anterior surfaces, or what we call *anterior duplicity*.

The most complete examples of duplicity yet known are found in this class, whose distinctive characters are, that two bodies, in a state of nearly equal developement, are placed exactly opposite to one another, with their sterna connected together, and with their abdominal cavities either partially or completely coalesced. Here, however, as in all the other classes, examples are found of gradations towards a state of singleness. For instance, the upper parts of the body being completely double, the lower are united, so that there are but three limbs, or only two lower or posterior limbs. And, in like manner, although in many cases the bodies are alike in size and other characters, yet there are many more in which one has so far surpassed the other, both in size and in stage of developement, as completely to fill up the series between this class and the decided heteradelphs. Whilst in the latter case we find close approximations to duplicity, there are even among the most perfect double monsters peculiarities which constantly recall to mind the parasitic attachment of the heteradelphs.

With this nearly perfect external duplicity there sometimes, but not always, corresponds an equal duplicity of organs. The umbilical cord may be single (Parsons, Otto), notwithstanding the heart is perfectly double. The two umbilical arteries belong but to one child; the umbilical vein bifurcates and enters both bodies. In another case (Cruveilhier), the single umbilical cord had two veins and four arteries, and the heart was externally single, and in its internal parts imperfectly double. In a third double monster (Otto), the umbilical cord had five vessels, two umbilical veins, and three arteries, and in this there were two hearts. In a fourth double monster the heart and umbilical cord were single. The bond of union, as far as the skeleton is concerned, is commonly a tough fibrous connection between the lower extremities of the sterna and the ensiform cartilages, which are set directly opposite to one another.

The rest of the sterna and the ribs are usually distinct, and the thoracic cavities are thereby separated. In this case there are commonly two separate and perfect hearts; but in the cases in which the sterna are more completely fused, or (as happened in one case) entirely absent (*Comm. Litt. Norimberg.*), only a single heart, or one partially double, with, for instance, two ventricles and four auricles, or otherwise malformed, is found. But it is particularly remarkable that in these, as in all other kinds of double monsters, there is no constant relation whatever between the respective states of the external and the internal organs, for the condition of the two digestive canals, even in those which are externally almost alike, is subject to still greater varieties than the condition of the heart. The abdominal organs are always in some degree connected; — the two livers are usually continuous.

A spleen, pancreas, and stomach are commonly found in each body, and each stomach has its own duodenum, which, after some length (being continued into the jejunum) unites with the other to form a single tract of small intestine, which again divides into two canals, leading respectively to the large intestine of each body. The lungs, the urinary, and the genital systems are always double. The most remarkable example of this class was the well-known Siamese twins. When exhibited, they were not exactly opposite to each other, but stood side by side, or, rather, obliquely one by the other; but this position, there can be little doubt, was acquired by the attempts which they had instinctively made to separate from each other in walking, or in lying and sitting down, and by the extension they had thus effected in their bond of union, which was considerably more slender than in any other yet described. It was quite impossible for them to remain always face to face; therefore their bodies acquired an oblique direction, in which they also moved. The consequence of this was, that the right limbs of the one and the left of the other individual were the principal organs of movement; and that the intermediate limbs, that is to say, the left of the one and the right of the other, remained merely passive (Dubois). The one individual was stronger than the other, and seemed to overrule him. But, nevertheless, in organic and animal relation of life they seemed to be independent of each other. Each had his own circulation of blood, his own respiration, and digestive functions. There did not seem to be a large anastomosis of vessels between the two bodies. But, by analogy with the foresaid cases, we may conclude that these twins are connected by the ends of their sterna, and by some of their abdominal organs. As a proof of this connection, may be adduced the result of the observations of Mr. Mayo, communicated at the *Conversazione of the College of Physicians March* 8th, 1831, that when either of the youths coughed, the bond of union swelled up in its whole length, proving that they had but one peritoneal cavity, of which a transverse prolongation passed through the connecting medium. And, therefore, I should conclude, that an attempt at separation could not be made with probability of success. The probability of having to cut through a piece of liver, or a peritoneal canal, must render an operation unwarrantable, unless, indeed, after the death of one of the bodies during the healthy state of the other. The case reported by König has scarcely authority enough to support a contrary opinion.

2. *Lateral duplicity.*

The varieties of form in anteriorly duplex monsters are closely limited by the partial nature of the union of the sterna and the nearly complete distinctness of the thoracic cavities, and hence of the whole upper part of the body. In the next class, which I call *lateral duplicity*, there is no such limit; and between the highest degree of duplicity found in it and the lowest, or that in which the duplicity is most nearly reduced to singleness, there is a far more numerous series of intermediate forms than in any other of the types of double monsters. In lateral duplicity, the two bodies are not set opposite to one another, but are turned sideways from one another. They have a common thoracic cavity, for the formation of which (at least, in the highest degree of duplicity,) the right ribs of one body, and the left of the other, proceed towards the anterior and posterior aspects, and are there connected with an anterior and posterior sternum. The best idea of the construction of this osseous fabric may be formed by supposing the two complete chests of two bodies to be set one against the other, and that then the anterior extremities of the right ribs of the right body, and those of the left ribs of the left body, unite with one sternum and pull it forwards, while, in the same manner, the left ribs of the right body, and the right of the left, unite on the posterior aspect with the other sternum, and carry it backwards. The consequence is, that the two vertebral columns are turned away from one another, and that the parts above and below the thorax are double. By the formation of this common thorax, the *lateral* is distinguished from the *anterior duplicity*, in which the thoraces are commonly connected only by the points of the sterna, and, as to their cavities, are separate. And with these differences of external construction, others not less important, of internal arrangement, coincide, which fully justify the separation of the two forms, however similar the external appearances of many of the examples of either may be.

The numerous varieties of lateral duplicity may be divided into two principal sets. The first begins with the complete duplicity of the whole body, and ends with its perfect singleness; in the second, the duplicity of the body remains, but the head gradually becomes single. The forms included herein, of which I have given ample accounts elsewhere, may be briefly summed up as follows.

1. Complete duplicity: — all the external parts and sometimes the abdominal and pelvic viscera double, — one common double-sized thoracic cavity, formed in the manner just described, and containing four lungs, and (in all cases with which I have been acquainted) only one heart. The examples of this form are very numerous, and are to be met with in all the large museums of Europe.

2. In the examples of this second group, which exhibits the first step towards singleness, one of the sterna may be traced in a succession of specimens, becoming gradually narrower, and permitting a closer approximation of the two corresponding upper extremities, till, in some examples, they are completely united, and there are found only three limbs above, with three or four below. The two juxtaposed scapulæ, for example, are merged into one, or they remain separate, but have only one humerus between them, and this splits below, to articulate with two fore-arms; or there is but one fore-arm, and this bears supernumerary fingers. In short by a great variety of modes there is a general tendency towards union of two of the upper extremities.

3. In the third group we have a repetition of the same series of changes in the lower limbs, as in the second was traced in the upper; here, as there, presenting numerous varieties, in the last and lowest of which only three lower limbs, and the third of these ill-formed, are found.

4. The third limb has now gradually disappeared, and, with a complete duplicity above the pelvis, there are but two limbs below it, and these well formed. In this class is placed, with many others, the *Ritta-Christina* monster, described by Serres, which lived to eight months, and the still more remarkable example mentioned by Buchanan, of a two-headed man, 28 years old, who lived in the reign of James III. of Scotland.

5. The union proceeding, and this simplicity of the lower part of the body being retained, examples come next in which the upper parts also are united; the two superfluous upper limbs being united into one, presenting a single upper-arm, with a double fore-arm and hand, or a single upper-arm, fore-arm, and hand with ten fingers, or only a mal-formed limb, or a mere projection, occupying the place of the superfluous limbs.

6. Even this last indication of duplicity of the upper parts ceases, a scapula only remains, or this also is absent; and next, one of the sterna having disappeared, and the vertebral columns having been connected on the corresponding side by their respective ribs united into single arches, these now become gradually shorter, and the columns approach each other more and more nearly, till they are connected by only a cartilaginous substance in the place of ribs, or are at some part fused together.

7. In this next group both the upper and lower parts of the body are single; the vertebral column is single below the cervical region, or exhibits only a trace of duplicity (to which something similar is often presented by the sternum), but at the cervical region becomes double, and on each portion bears a head. Of this also I have published many examples.

8. In the eighth group the extent of that cervical part of the column which is double becomes less and less.

9. In the ninth group, the two heads are seated on an apparently single neck, in which all the cervical vertebræ are single, or only bear traces of duplicity, except the first two, or the first alone.

10. Hitherto the duplicity of the head was perfect; in this group the two heads also begin to coalesce, and, in a considerable number of cases, gradations are traced in which the adjacent ears are very closely approximated, and the heads are united behind. Then there are cases in which one ear only is placed between the adjacent surfaces of the two heads, and this disappears gradually, and at last totally. Next in order are the cases in which the adjacent ears being lost, the two adjacent and middle eyes first become very close, and then occupying one orbit finally coalesce. Next come those cases in which there is such a union of the heads, that the two upper jaws are articulated with one lower jaw; and, lastly, those in which the head is doubled only in individual parts or in which

there is one perfect heart, with some imperfect part or parts of another attached to it.

11. The eleventh group of this division includes the cases of lateral duplicity, in which the body is single in the middle, but doubled above and below (or in brutes anteriorly and posteriorly). In these, which are of rarer kinds, a single neck bears two more or less completely separated heads. The vertebral column is for a considerable length single, but at its lower part again divides, and bears two sets of lower extremities.

12. In the twelfth group the body is single above and doubled below.

13. In this there is a tendency towards singleness, or even complete singleness, of the head, but all parts of the trunk and all the limbs are doubled, an arrangement by which, as already stated, these form a series entirely distinct from the rest. In some of these cases the two heads are found coalesced below; in others, to which the name of *janiceps* has been given, one face is directed backwards and the other forwards, the remainders of the two heads being merged into one; in others, one face is *perfectly*, the other very *deficiently*, developed; in others there are only the indistinct traces of a second head presented in the existence of one or two ears on the posterior aspect of the more perfect one; in others, this trace of duplicity is still less evident; and, lastly, in the remainder of the group, it is entirely lost, and one head only, which may be well or ill formed, is found upon the double body.

3. *Inferior duplicity.*

My third division of double monsters includes the cases in which there are two complete bodies with the lower portions of their respective trunks united, so that there is a head with upper extremities both above and below (the bodies being placed in the same straight line) and on either side of the part at which they meet two lower limbs. One may best conceive this arrangement by supposing two children stuck together by their buttocks, and so fixed with wide-spreading lower limbs, as may be seen in *fig.* 146. of the second volume of this Cyclopædia. A common body is thus formed with a head at each end, with two upper limbs both above and below, and with two lower limbs, one belonging to each fœtus on the right and two on the left of the united portions. A few cases only of this remarkable monstrosity are recorded; and in these the duplicity was not always complete, but exhibited in some the same tendency towards singleness as was noticed in the others. Thus in some there were but three lower extremities; in others there were but two, or two with a third ill-developed on the other side: and, again, in other groups there were those which have a perfect head at one end of the trunk, but an imperfect one or none at all at the other.

These monsters have been known to live a considerable time, their capacity for life being probably owing to the separation of the hearts and the absence of malformation in the more important organs of the body. The umbilical cord is single, and never has a double set of vessels; an apparent proof (confirmed by similar examples in other classes) that the one body is not formed of the materials of two; a conclusion which is supported by the coincident singleness of the anus and urinary bladder, and the union of the intestinal canals.

4. *Posterior duplicity.*

The fourth chief form is *posterior duplicity*, in which two bodies are united by their backs, or a part of them. The union may be at the pelvis (which is most common), and occurred in the well-known Hungarian sisters, who lived to their twenty-second year; or at the back of the vertebral column, or at the back part of the heads.

5. *Superior duplicity.*

The fifth is the *superior duplicity*, in which the two children are connected by their skulls, the bones of which are united so as to form a single skull. In these also the place of union varies greatly. The frontal bone of one coalesces with the parietal or the occipital of the other, or the foreheads are attached to one another, or the side of one head to the front of the other. But all these are very rare, and of each kind only one or two examples can be found on record.

All these are true double monsters. Of *tripled-bodied monsters* but one instance is known in the human subject (*Atti dell' Academia de Cattania*, t. viii. p. 203., 1834).

To conclude the description of duplicity, those which occur in individual parts of the body, the rest being single, viz. in the head, chest, abdomen, and limbs, ought to be recorded; such as, for example, two mouths, supernumerary teeth and horns, two œsophagi or duodena, double hearts, or supernumerary cavities in one heart otherwise well formed, a double penis and urethra, a double clitoris, supernumerary breasts, kidneys, vertebræ, ribs, fingers, toes, or whole limbs. But for all these I refer to my monograph.

At present I prefer to give all those considerations upon the origin of double monsters, of which this highly interesting subject is capable. From all the facts I have published, I point out the following *generalisations*: —

The double monsters form collectively one class of organic beings, which, however different in their several degrees of malformation, may be arranged in one continued series. As the lowest degree of duplicity, may be mentioned that of a single part of the body; for example, a double or supernumerary finger; as the highest, a complete double monster with two heads, four upper and four lower limbs, and two trunks, such as the Siamese twins. And between these two extremes there are different forms of duplicity, which gradually run one into the other.

There is no positive or constant relation between the external and the internal organs as to their degrees or modes of duplicity. In the completest duplicity of the exterior, for example, the heart is often single, or even shows signs of having been arrested in its developement; and, on the other hand, in the more nearly single forms, the heart is usually either partially or completely double. The histories of the cases of anterior and lateral duplicity, which I have given in my monograph, furnish abundant proofs of this. Nor is there any closer relation between the condition of any other internal organ and that of the exterior, than there is between it and the heart; for in nearly complete external duplicity any of the internal organs may be single; when there are two trunks indeed, the urinary and genital organs are commonly double; but as for the stomach, the liver, and the lungs, the correspondence between them and external duplicity follows no other rule than that where there are two necks there are two tracheæ and two œsophagi, and as a consequence the lungs and stomach are also doubled. When in like manner the stomach is double, each has its spleen and pancreas; but the state of the liver is very variable; sometimes there are two, sometimes but one with a single or double gall-bladder; and these differences often occur in the same form of external duplicity.

Parts placed on the surface of the body are more liable to multiplication than the internal organs, and duplicity of a single part is therefore much less rare than the formation of a complete double body. The upper half of the body is more frequently doubled than the lower, probably in consequence of its earlier developement and the admitted preponderance of the upper parts of the body. The union of the two bodies takes place only between similar parts. The more each of the bodies is developed, the less is the bond of union between them, as the examples of the Siamese twins and the Hungarian sisters sufficiently prove. And with this law is connected another, namely, that the probability of growing up is greater in the same proportion as the bond of union is smaller, and the coincident fusion of internal organs less, as these two and other double monsters prove. So also the further the several organs are from the situation at which the bodies are united, the more perfect they are, — one body is almost always less developed than the other: in the heteradelphs this is always the case, and in others the difference between the two bodies, though less evident, is scarcely less constant than in them. There are not commonly any signs of a double monster having been at first two individuals. For except in the cases of posterior and superior duplicity, and some singular examples of attachment of the umbilical cord of one fœtus to the head or the body of the other, there is never more than one placenta and one cord, and the latter usually contains only a single set of vessels, which divide when they reach the abdomen. And even in the posterior and superior varieties of duplicity it is not yet certain that there are two placentæ; in some cases the placenta was positively single, and in the remainder it has very rarely been examined. A last general rule is that in double monsters the twins are of the same sex. There is no well proved exception to this important rule.

What explanation can be given, after all these facts, of the origin of double monsters? On this subject, three hypotheses ought to be mentioned: 1. The double monster has been supposed to have proceeded from two distinct embryos, which have become united in the course of development; 2. It has been held to have originated in a single germ, which has become double, or has been subdivided; and 3. The germ has been regarded as abnormally compound from the first, implying that the organs and parts composing the double monster are at once produced from this germ, without either separation or coalition of its parts other than belong to the natural process of developement. On the comparative merits of the first and second hypotheses, as parts of the general doctrine of monsters, one of the most interesting physiological discussions extant is recorded in the *Mémoires de l'Académie des Sciences de Paris*, between 1724 and 1743. The chief disputants were Lemery and Winslow; the contest lasted nineteen years; it engaged the attention of all anatomists, and called forth writings by Haller and a crowd of authors of less note, and was only terminated by the death of Lemery. Every argument that could be founded on the knowledge of those days was brought forward, and the subject was, for the time, utterly exhausted; but the facts accumulated in later years have furnished such volumes of additional evidence, that the same question, between original and acquired monstrosity, as far as it relates to double monsters, may even now claim to be discussed.

It is certain that two ova may be formed in one Graafian vesicle (Von Baer, Bischoff, Bidder). The equally well-known fact, that the common fowl sometimes produces double-yolked eggs, naturally led at one time to the opinion that the formation of double monsters might be attributed to the developement and subsequent union of the embryo in each yolk; an opinion which has been adopted by some on very insufficient grounds, as it does not appear to be warranted by any direct observations made upon the result of the incubation of double-yolked eggs, and is at variance with much of what is known of the structure and mode of union of the two embryos composing a double monster.*

* I have here made use of the words of Professor Allen Thompson, who, in a remarkable memoir upon *double monsters*, published July, 1844, in the *London and Edinburgh Monthly Journal*, fully entered into the topic, and illustrated the genesis of double monsters by some very interesting observations. I lament that he was not acquainted with my monograph upon the same subject, nor with the succinct account which Mr. Paget has given of it in the British and Foreign Medical Review for October, 1841. He would have found in it a great deal in corroboration of his own opinions, in which I universally agree with him.

C. F. Wolff has distinctly affirmed, that a double-yolked egg is equivalent to a double ovum; that the produce of its incubation would be twins; and that a double monster can only proceed from a single yolk containing a double germ. Examples of double embryos of birds sometimes occur at the full period of incubation, in which both are complete, and there is no union, excepting at the umbilicus. It is barely possible that each of these embryos may have been developed from a separate yolk, and that in the course of incubation the two yolks have come to coalesce, in consequence of external pressure, or other causes. Towards the conclusion of the period of incubation, when the yolk usually enters the abdomen of the fœtus, we may suppose, in the case before us, a partial entrance of the common yolk into the abdomen of each embryo, and thus, upon the subsequent contraction of the umbilical aperture, the union of the two embryos may be effected. We learn, from the accurately-detailed observation of C. F. Wolff, previously referred to in my monograph, that two completely separate fœtuses may be formed in the bird's egg upon a single yolk, and within a single germinal and vascular area. The egg, in this instance, had been incubated six days, and both the embryos were at once so complete and so distinct, that there is no reason to believe they would have been united till the period when the entrance of the yolk into the abdomen of both, and the contraction of the umbilical apertures, had brought them together.

In a dozen double-yolked eggs, which Prof. Allen Thompson brought to incubation, he never succeeded in obtaining a double monster, nor even two embryos, at the full period, from any of them. In several instances he found that one yolk only had been productive.

All this proves that such double-yolked eggs may produce twins, but that the formation of a double monster is not dependent on them. It is highly probable that in the same manner, in Mammalia, the arrival in the uterus of two impregnated ova, in close proximity with one another, will be attended with the production, not of a double monster, but of twins.

The complete fusion of these twins seems to me quite impossible. One of my chief arguments against the hypothesis of fusion of originally separate germs is the important fact, which I derive from my own investigations and from those of others, that double monsters form one series, among whose several members the degrees and modes of deviation from singleness gradually increase, and pass, without one abrupt step, from the addition of a single ill-developed limb to the nearly complete formation of two perfect beings. Now if this be true, no hypothesis can be acceptable if it do not plausibly explain the origin of the whole series of double monsters, or if, though it may suffice to explain the facts in one part of the series, those in another part are opposed to it. And here is a fair objection against the hypothesis of fusion of two originally perfect and separate embryos. Grant that we might explain by it the formation of several of the more perfect instances of duplicity; still, if the same hypothesis is altogether opposed by the simpler forms of duplicity, it is surely not tenable. For example, it cannot account for the existence on a child's sacrum of a shapeless mass, containing an isolated portion of intestine, as in Mr. Hanley's case. And still less can it explain the existence of a superfluous limb; for the limbs are mere off-shoots, and are produced at so late a period, that if we could imagine two embryos to come in contact by their shoulders or pelvis, and a fusion of those parts to take place, we should still have to explain how one of them, leaving only an arm or a leg behind him, could for the rest of his substance, head, trunk, and all, wholly disappear.

It was a main objection against the doctrine of Lemery, that if two germs came in contact by accident (as he supposed), they could not exhibit any regularity in their mode of attachment, but faces would be forced into chests, abdomens into spines, and so on. The moderns, who adopt the same hypothesis, suppose that the ova come in contact not by accident, but by an *attraction de soi pour soi,* of which the influence is, that the two ova being by accident set face to face or back to back, or in any other way *similia similibus,* will be drawn to each other, and will unite by similar parts. But, with all respect for the authority of M. Geoffroy St. Hilaire and his disciples (as Mr. Paget elegantly said in his abstract of my monograph upon double monsters), who regard this as "la règle suprême de tous les arrangements et de toutes les modifications organiques chez les êtres composés," I confess that I can find no good evidence that such an attraction exists. I can see in it nothing more than a very happy expression of a fact, which it in no wise explains. The extraordinary notion of MM. Delpech and Coste, that such an attraction may be the result of electric currents, is certainly no evidence of its existence, this being entirely imaginary. And the reasoning in its favour seems no better than the facts, for I can find nothing but this kind of circle: monsters adhere by similar parts, therefore there is an attraction *de soi pour soi;* there is then such an attraction, and therefore double monsters so adhere. I believe, therefore, that such an attraction is hypothetical; and if it be so, surely the hypothesis which involves it and an accident as essential elements is less probable, as well as less sufficient, than that which I maintain. It is scarcely better than Lemery's, of mere accident; for it requires not only the accident of a particular position of the ova, but that of their being of the same sex, which has been said previously to be the general rule for double monsters. After all this, we conclude with the words of the learned Wolff, published in 1773: — "Patet, igitur, monstra composita non sic oriri, ut aliquando duo separati integri embryones fuerint, qui dein contingentes et compressi, partibus eorum nonnullis destructis, aliis coalitis et commixtis, concrescerent in unum novum compositum corpus; ea vero, quæ vel defectu partium vel insolita structura monstra sunt, non ita fieri ut prius integri et naturales embryones fuerint, qui deinde per causas accidentales ad generationem non pertinentes mutilati vel transmutati fuerint; sed necesse esse, ut utraque monstrorum genera a primis suis initiis jam ejusmodi monstra fuerint."

If we are right in not admitting the existence and the fusion of two distinct germs, we necessarily adopt the opinion that only one germ has been formed, and that in this excess of formative power lies the cause and origin of every monstrous duplicity. Mr. Allan Thompson demonstrated, in coincidence with Wolff, Von Baer, and Reichert, as may be seen in the wood-cut (*fig.* 629.), that

Fig. 629.

(*After A. Thompson.*)

upon one yolk, and in one germinal membrane or blastodermatic vesicle, there may be formed, in birds, two primitive grooves, which, in their ulterior increment, shall probably form a double monster, as may be seen in a goose's egg, after five days' incubation, represented after Allan Thompson, in *fig.* 630. By the formation of such a double primitive groove in a single ovum, we may explain the origin of the principal types of double monsters; and on this point a recent observation of Valentin seems particularly worthy of notice, viz. that in which an injury, inflicted on the caudal extremity of an embryo on the second day, was found, on the fifth, to have produced the rudiments of a double pelvis and four inferior extremities. But if we admit this cause for those large and principal types, we must acknowledge that it is insufficient for the heteradelphs, and for all those cases in which, the body remaining single, some parts are

(*After A. Thompson.*)

double. For these the excess of formative power is the only explanation we can give. We understand, under this name, not the *nisus formativus* of the ancient physiologists, working as a *Deus ex machina*, but the physical and vital *metamorphoses materiæ*, to which the formation of a new being ought to be attributed. Those who are fond of the modern nomenclature may name it, if it pleases them, *typical* or *organic power*. But enough, we admit such a power, of whatever name it may be, and contend further, that different degrees or quantities of excess lie at the origin of all the cases of double monsters, the degree of excess determining in each the degree of duplicity. If a certain excess of power be admitted capable of producing any one case of duplicity, other amounts of excess may be believed capable of producing all the other cases which differ from it only in degree; and I meant to have proved, in my monograph, and in the succinct survey I have given of double monsters in this Article, that all double monsters may be referred to differences in degree of deviation from the normal singleness.

But in many double monsters we see excess in one part and defect in another, so that we must suppose, in our hypothesis, that in these cases the power, more or less excessive in quantity, is also wrongly distributed. Nor is this inconceivable; for since, in the normal developemental power, we must imagine at least two elements, *quantity* and *distribution*, and must acknowledge that, for the attainment of a perfect result, the quantity must be distributed in definite proportions to each part, so it is not improbable that, in certain circumstances of fault in the ovum, a normal or an excessive power may be distributed disproportionately in the several parts.

To sum up, therefore, our reasons for rejecting the hypothesis of fusion of ova in favour of that of excess or irregular distribution of developemental power, for preferring to regard them as examples rather of singleness tending to duplicity than of duplicity tending to singleness, are briefly these: that it is probable that the whole class of monsters by excess owe their origin to different degrees of one common fault, and consequently that the explanation of their origin ought to be the same for all; that no kind of fusion can account for the production of supernumerary individual organs, the rest of the body being single; but that it is not impossible that excess of power in the ovum, which all admit can alone explain the lower degrees of duplicity, may, in proportionally higher degrees, perhaps by the formation of two primitive grooves, produce the more complete double monsters, or even two such separate individuals as are sometimes found within a single amnion.

Bibliography. — On account of the length of this Article, and the great number of books upon the subject, I shall omit the Bibliography, and refer to the foot-notes as well as to the manuals of Meckel, Rokitansky, Geoffroy St. Hilaire, von Ammon, and my own, in which the bibliography is duly noticed.

(*W. Vrolik.*)

TESTICLE.—(Human Anatomy). Gr. ὄρχις; Latin, *Testis — Testiculus;* French, *Testicule*; German, *Hode;* Italian, *Testicolo*.

The testicle is the gland by which the semen or spermatic fluid is secreted. Two in number, and contained within the scrotum, these organs are suspended at a variable and unequal distance from the abdominal rings, one testicle, generally the left, hanging a little lower than the other. This arrangement prevents collision between these organs when the thighs are suddenly approximated; one testicle slipping above the other, and thus eluding violence. In cases of transposition of the viscera and blood-vessels, it has been observed that the right testicle hangs lower than the left.

The shape of the testicle of an adult is that of an oval with flattened sides. The organ has two extremities, an antero-superior, and a postero-inferior; and two lateral surfaces. Its position in relation to the body is rather oblique, its long axis or antero-posterior diameter passing from above downwards and a little inwards. Its edges and sides are convex. Its upper extremity is rounded and capped by the epididymis, which rises above the body of the gland like the crest on a helmet. According to Cruveilhier the testicle measures two inches in length, one inch in breadth, and eight lines in thickness. Sir Astley Cooper makes its long diameter two inches; its transverse, an inch and a half; and its lateral, one inch and one eighth. I have found the mean dimensions of the testicle to be one inch and three quarters in length, one inch and a quarter across or in breadth, and one inch in thickness or from side to side. Meckel states its average weight to be four drachms, and Sir A. Cooper about an ounce. I have found the mean of these two estimates, viz. six drachms, to be the ordinary weight of the sound testicle of a healthy adult.* There are few organs subject to greater variations in size and weight than the testicle, even in men of the same age and constitution. The testicles also of the same individual rarely agree, the volume and weight of the left being, in general, greater than those of the right. I weighed the testicles of six men, two of whom were killed by violence, and found the left gland heavier than the right in five; in neither of these instances, however, was the difference more than a drachm. The organ feels tense, compact, and slightly elastic. Its degree of consistence depends more on the tension of the tunica albuginea than on the proper substance of the gland. It is a good deal influenced by the quantity of seminal fluid contained in the tubular structure, and its state of activity or rest; the gland being tense and tumid when the organ is exercised and the tubuli are distended, and soft and flaccid, when they are empty and the gland inactive. The parts composing the testicle may be described under four heads: — 1. The protective parts or tunics; 2. The proper glandular or secreting structure; 3. The excretory parts; 4. The vessels and nerves.

1. *The Protective Parts or Tunics.* — *The Tunica Vaginalis.* — This is a delicate serous membrane in the form of a shut sac, which consists of two portions; an outer one, the *parietal*, which is free and loose; and an inner, reflected, *visceral* or testicular portion, which closely invests the gland. The two portions are connected and continuous with each other. The outer one loosely invests the whole of the testicle except its posterior edge and inferior extremity, parts where the membrane becomes attached to the gland. It is connected with the testicle at about five lines from the lower extremity, and the junction of the two portions is marked by a white and rather irregular line. The uncovered portion of the organ corresponds to the original attachment of the gubernaculum. On the inner side of the gland the membrane, after investing the lower part of the cord to a greater or less extent, is reflected to the epididymis just below its head, and to the posterior edge of the body of the testis, being there separated from the epididymis by the vas deferens and blood-vessels of the gland. On the outer side the membrane entirely covers and closely invests the epididymis, and forms a cul-de-sac, which isolates its middle from the posterior border of the testicle, and in cases of hydrocele is often distended into a pouch. At the bottom of this sac the tunica vaginalis on the two sides comes into close contact, and sometimes there is a communication at this spot between the two. The smooth and polished surface of the shut sac thus formed by the tunica vaginalis is lubri-

* This nearly accords with Krause's estimate (Müller's Archiv. 1837.) — who found the mean weight in five instances to be 354·4 grains, or five drachms, two scruples and fourteen grains.

cated by an albuminous fluid, having the ordinary properties of the secretions of the other serous membranes. The office of this membrane is to facilitate the movements of the gland, so as to enable it to elude pressure and escape violence.

In some adult subjects the tunica vaginalis, which was originally a process from the serous lining of the abdomen, still retains its connexion with that cavity. When the communication is free, the sac is very liable to receive a protrusion of some of the contents of the abdomen, and become the seat of congenital hernia. Sometimes the communication continues through a contracted tubular canal, which, though too narrow to admit the transit of any of the viscera, is open to the passage of fluid. In other cases the obliteration is partial, one or more isolated serous sacs being left along the cord. It more often happens, however, that after the upper aperture of this process has closed a considerable part of it below remains unobliterated, so that the tunica vaginalis extends for some distance upwards in front of the cord. Frequently, also, although the obliteration is complete, remains of the prolongation may still be found in the form of a slender whitish filament, or fibrous process, which is lost in the areolar tissue in the anterior part of the cord, but may sometimes be traced as far as the tunica vaginalis.

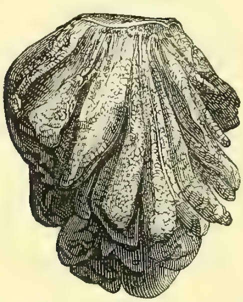
A small body of an irregular shape and variable size, and of a pale red or pinkish hue, is commonly found attached, often by a thin pedicle, either to the upper extremity of the testicle, or at the angle where the tunica vaginalis passes from the body of the gland to the epididymis. It is composed of a duplicature of this membrane, containing some fine areolar tissue and a number of small vessels. It occasionally contains a little fat. I have seen this little body in the testicle of the fœtus whilst in the abdomen, and, in early life, it is often of proportionally larger size, and of a deeper red colour than in the adult. It is quite distinct from the pedunculated cysts often found attached to the head of the epididymis. This little appendage to the tunica vaginalis seems to correspond with, and to be a type of, the remarkable omental process attached to the superior part of the testicle in the *Rodentia* and other animals. That it is an unimportant structure in the adult, is shown by its being frequently wanting. It may be of use, however, by slightly increasing the secernent serous surface.

The tunica Albuginea, or *Tunica Propria*, is a dense, tough, inelastic membrane, composed almost solely of white fibrous tissue, analogous to the sclerotic coat of the eye. It completely invests the body of the testicle, but not the epididymis. Its external surface is covered by the tunica vaginalis reflexa, to which it intimately adheres. This tunic is divisible into two layers, which can be separated only by a tedious dissection, but which in certain animals may be detached without difficulty. The branches of the spermatic artery and veins ramify in the substance of the tunica albuginea, in canals bearing in their arrangement some analogy to the sinuses of the dura mater, which membrane the outer layer is supposed to resemble. The smaller vessels are chiefly distributed on the inner layer, which owing to its vascularity has been compared to the pia mater investing the brain. At the postero-superior border of the testicle, and a little to its outer side, the tunica albuginea forms an internal projecting body or process, which lodges the blood-vessels and a portion of the glandular structure of the testicle, called the *rete testis*. This body is named, after the anatomist who first described it, the *Corpus Highmori*. It has since, however, been called by Sir A. Cooper the *mediastinum testis*, and he describes it as being formed by the tunica albuginea, which at that part is divisible into three layers. The first layer turns upon the spermatic cord, and unites with the sheath which covers the vessels. The second layer unites with a similar layer on the opposite side, and forms a thick substance, between the fibres of which interstices are left for blood-vessels and absorbents, whilst the internal layer, uniting with that on the opposite side, as well as with the preceding layer of the tunica albuginea, forms the process called mediastinum, which projects into the testicle between the tubuli, and it is in this substance that the seminal canals of the rete are placed. The mediastinum is therefore composed of two bodies; the upper placed towards the spermatic cord, the lower towards the centre of the testicle: in the upper are placed the blood-vessels; in the lower, the canals of the rete. Its length varies from six to eleven lines.

II. *Glandular or Secreting Structure.*— The glandular part of the testicle is very simple, and its tissue is more easily demonstrated than the structure of most other glands. It consists of numerous seminiferous vessels or tubes, supplied with blood-vessels, lymphatics, and nerves. Its colour is a greyish yellow or brown, more or less tinged with blood, and is paler in infants and old men than in adults. The tubes are collected into numerous lobes or lobules, invested by a fine areolar tissue, which, detached from the interior of the tunica albuginea, penetrates the gland, and sends out lateral processes forming septa, which separate and sustain the lobules. These septa at their origin partake of the fibrous character of the tunica albuginea, but as they converge towards the superior border of the testicle, occupied by the corpus Highmori, they become finer, and are gradually resolved into a delicate areolar tissue. The septa are traversed by numerous blood-vessels, which minutely divide in them before being distributed on the seminiferous tubes. Sir A. Cooper states, that the inverted portion of the tunica albuginea, forming the mediastinum testis, sends forth numerous ligamentous cords, some of which pass to the anterior edge of the testis; whilst others form shorter processes to support and invest the lobes, being met by similar ligamentous cords from the inner surface of the tunica albuginea. I have not been able to make out any such ligamentous processes passing into the substance of the testis, as are represented in Sir A. Cooper's work (part i. pl. 2. fig. 3), which I have no doubt is an exaggerated view of the preparation from which it was taken. The cords described appear to me to consist chiefly of blood-vessels supported by slight fibrous processes from the tunica albuginea and areolar tissue. In a well-injected testicle very little tissue of the nature of ligament can be found between the lobes. The secreting structure of the testicle, like the texture of many other glands does not possess much common sensibility. When exposed in disease it may be probed and injured with the forceps without pain.

Tubuli Seminiferi. — These tubes, which form by far the greatest part of the bulk of the glandular structure of the testicle, are very numerous, and radiate from all parts of the circumference of the organ towards the mediastinum, making numberless convolutions which progressively diminish as they approach the rete testis. Two or more of the tubuli, being collected together and invested by a common tunic of condensed areolar tissue, form a lobe or lobule of a conical form, its apex terminating at the corpus Highmori. The lobes thus formed are

Fig. 631.



The lobes attached to the mediastinum, but artificially separated from each other. (From a preparation in the Hunterian Museum, formerly in Sir A. Cooper's collection.)

not entirely distinct, but communicate with neighbouring lobes: the processes investing them are therefore incomplete, and the lobes cannot be separated from each other without division of some of the seminiferous tubuli. Krause estimates the number of the lobes as varying from 404 to 484.* The tubuli are of a white colour and uniform size, but their calibre differs in different subjects, and varies a good deal according to the age of the subject and the state of activity of the testicles, being larger in young adults and when distended with semen, than in old persons and when the gland is in a state of rest. The size of the ducts also often differs in the two testicles of the same subject. In general the calibre of the tubuli corresponds to the size of the testicle. Observers do not exactly agree in their estimates of the diameter of the tubuli. The average diameter of the uninjected canal is estimated by Müller at $\frac{1}{18}$ of a line; by Lauth* at $\frac{1}{185}$ of an inch. Krause found the tubuli, when filled with semen, to measure about $\frac{1}{12}$ of a line, and in old men and youths $\frac{1}{16}$. Huschke† estimated the ordinary thickness of the whole tube from $\frac{1}{13}$ to $\frac{1}{15}$ of a line, and that of the walls from $\frac{1}{100}$ to $\frac{1}{111}$. Owing to the stoutness of the basement membrane, the thickness of the walls of the tubes is considerable as compared with the secreting ducts of other glands, and this accounts for the tubes being able to resist the pressure of a column of mercury in injections. Monro reckoned the number of the seminiferous tubes at 300; Lauth made the average number 840, and he estimated the mean length of all the ducts united at 1750 feet. He found the individual ducts to vary in length, the mean being 25 inches. Krause estimated their entire length at 1015 feet. The membrane composing the tubuli is continuous with the mucous surface of the genito-urinary system. It is lined with epithelium, and the spermatozoa are developed from the epi-

† Encyclopédie Anatomique, t. v. p. 347.

thelial cells. There is no appearance of an intertubular substance; the ducts are merely connected by a loose network of vessels, and consequently readily admit of being separated and unravelled. The tubes, when successfully injected with quicksilver, form a beautiful anatomical preparation. Sir A. Cooper succeeded in filling the tubes with size injection; but he has not described the mode in which it was effected, and other anatomists have failed in similar attempts.*

When the tubuli seminiferi are unravelled, they are found to divide and form numerous anastamoses, which increase in frequency towards the circumference of the testicle. (See diagram, *fig.* 633. a^1 a^1). The tubuli thus form one vast network of communication, so that it is impossible to isolate completely either a duct or a lobule. The credit of making this interesting discovery of the anastamoses of the seminal tubes is due to Lauth. In only one instance did he succeed in finding a duct, terminating in a blind pouch, and this he regarded as exceptional. Blind ends have been found, however, more frequently by Krause. The anastamoses of the tubules have been observed in the rat and other animals as well as in man. The convolutions of the seminal tubes diminish in number as they approach the mediastinum, and cease altogether at a distance of from one to two lines, where two or more unite to form a single straight duct, termed *vas rectum*, which joins the rete testis at a right angle (a^2 a^2). The vasa recta are very slender, and easily give way when injected: their calibre, which is greater than that of the seminal tubes, is estimated by Lauth at $\frac{1}{108}$th

Fig. 633.

* Sir A. Cooper's beautiful preparations of the testicle are preserved in the Museum of the Royal College of Surgeons of England.

of an inch. Haller reckoned their number at twenty, which is, however, too few.

Rete Testis, as its name implies, consists of a plexus of seminal tubes, which occupies the corpus Highmori, or mediastinum testis. The vasa recta, after penetrating the walls of this body, terminate in from seven to thirteen vessels which, running parallel to each other in a waving course, and frequently dividing and anastomosing, form the *rete testis.* (b). Lauth found the mean diameter of the vessels of the rete in injected preparations $\frac{1}{72}$ of an inch. According to Prochaska, these vessels are supplied with valves, but such is not the case. Small dilatations, however, are often found in different parts of the plexus.

III. *The Excretory Parts.*—The *epididymis*, a continuation of the testicle, is a body of a crescentic form, divided into an anterior and upper extremity, called *head*, or *globus major*, which is firmly attached to the testicle; a middle part or *body*, which is less in size, and separated from the gland by a pouch of the tunica vaginalis; and a *tail* or *globus minor*, connected to the testicle by areolar tissue. The volume and weight of the epididymis vary in different subjects, but are proportionate to the size of the testicle. It is longer than the testicle, measuring about two inches in length and four or five lines in width. Its name (from ἐπὶ upon, and δίδυμος testis,) indicates its position, which is along the postero-superior border of the gland. The epididymis is chiefly made up of seminal canals connected and supported by a firm resisting areolar tissue. The ducts which spring from the upper part of the rete testis to form the epididymis are termed *vasa efferentia.* They are usually about twelve or fourteen in number, but vary from nine to thirty. The inflections of each of these efferent ducts are so arranged as to form in the head of the epididymis a series of elongated conical figures called *coni vasculosi.* These ducts, at their commencement, run straight for a distance of about one or two lines, when they form convolutions which become more numerous and close as the ducts recede from the testicle. Their length varies, the upper being the shortest. Lauth found their average length to be seven inches four lines, and calculating their number at thirteen, he makes the united length of the vasa efferentia nearly eight feet. He states that the efferent ducts diminish in size from their commencement to their termination in the canal of the epididymis, where they are less than the seminiferous ducts of the testicle. (*Fig.* 634.) As in the rete, round dilatations of variable size are often met with in these ducts. (*Fig.* 632., *e e.*) The efferent ducts, after forming the coni vasculosi, successively join a single duct, the canal of the epididymis, at irregular distances, the intermediate portions of the duct varying in length from half an inch to six inches. The efferent ducts are more slender than the canal of the epididymis, and frequently give way under the pressure of the column of mercury when injected. The body and tail of the epididymis are entirely made up of the convolutions of the single canal in which the

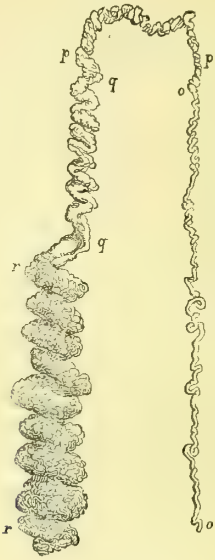
vasa efferentia terminate, closely connected by areolar tissue. Monro described this canal as gradually increasing in size from the head to the tail, and he estimated its calibre about its middle at $\frac{1}{80}$ of an inch. Lauth states that its size is subject to great irregularities in different parts and in different subjects. This anatomist has particularly described the convolutions of this duct, and has shown that they are regularly arranged in four series, which successively increase in size; the first being the smallest, and the fourth the largest. The arrangement will be understood by reference to the subjoined figure. Monro estimated the length of the canal at thirty feet eleven inches. Lauth found its mean length to be nineteen feet four inches eight lines. The parietes of the canal are strong, and bear considerable resistance. The canal of the epididymis terminates in the excretory duct of the testicle, the vas deferens, and is usually contracted at the part where the two join, which accounts for the mercury when forced into the vas deferens being often arrested at this point. It was calculated by Monro that the semen, before arriving at the vas deferens traverses a tube forty-two feet in length. Lauth, however, makes the whole distance but little more than twenty-two feet.

Vasculum aberrans. — This name was given by Haller to a blind duct or cœcal appendage often found connected either to the epididymis or vas deferens. It is more commonly attached at the angle formed by the

Fig. 635.



Canal of the epididymis partly unravelled, to show the four series of inflections which the duct undergoes in the several divisions of the epididymis.

termination of the former in the latter. (*Figs.* 632., and 633, *h.*) It forms a convoluted duct as large as the canal of the epididymis, which is contracted at its insertion, and terminates in a blind and often dilated extremity. Sometimes after being dilated for a certain distance it diminishes, and becoming very minute, is lost in the areolar tissue of the cord. It usually passes up the cord for about two or three inches, but has been found to extend as far up as the brim of the pelvis. The length of this appendage when unravelled varies from one to twelve or fourteen inches. The vasculum aberrans is not constantly present; indeed, Monro found it only four times in sixteen; but I believe, with Lauth, that it exists more frequently. Occasionally there is more than one, and as many as three have been found both by Lauth and Sir A. Cooper. Hunter regarded these ducts as supernumerary vasa deferentia, of a nature similar to the double ureters.* Müller states that their office is evidently the secretion of a fluid which they pour into the epididymis.† We have no evidence, however, that the duct serves any particular office.

Vas deferens, — the excretory duct of the testicle, commences from the tail of the epididymis, and terminates in one of the ejaculatory canals behind the bladder, being in length from fifteen to sixteen inches. Arising

* Works by Palmer, vol. iv. p. 24.

† Physiology, trans. by Baly, vol. i. p. 45

from the contracted part of the canal of the epididymis at an acute angle, it ascends along the inner side of this body, from which it is separated by areolar tissue and the spermatic arteries and veins. A right or left testicle may thus always be distinguished by the circumstance that when the testicle is in position, the vas deferens is situated on the inner or mesial side of the organ. In this part of its course, for the distance of about an inch and a half, or more, the vas deferens forms numerous convolutions, (*figs.* 632., and 633, *i.*), which gradually cease as the duct mounts above the testicle. The inflected part of the vas deferens, when unravelled, was found by Lauth to measure six inches and a half. It afterwards takes a direct course (*k*) up the spermatic cord to the inguinal canal, passing behind and at a short distance from the spermatic arteries and veins. On entering the abdomen at the internal ring, it quits the spermatic vessels and descends into the pelvis, passing at first by the side of, and afterwards behind and below the bladder, on the inner side of the corresponding vesicula seminalis, the excretory duct of which it joins at an acute angle, to form the ejaculatory canal. The canal of the vas deferens is extremely fine, and its walls are nearly uniform in thickness until it reaches the vesicula seminalis. It is lined by a fine membrane of a mucous character, which is continuous with the urethra. This membrane forms longitudinal folds. The vas deferens is round and indurated, — harder than any other excretory duct in the body, by which character it is easily distinguished, when handled, from the other parts constituting the spermatic cord. Many anatomists have entertained the opinion that the parietes of this duct are muscular. It is distinctly so in the bear, bull, and other animals. On careful examination, however, of sections of the human vas deferens with the microscope, I could discover nothing more than simple fibrous tissue. Huschké makes three layers of fibres; two longitudinal, and one circular, situated between them; the latter being the thickest. The duct has an external investment of condensed areolar tissue.

IV. *The Vessels and Nerves.* — *Spermatic Vessels.* — The spermatic arteries, the chief vessels supplying the testicles, arise in pairs, at a very acute angle, from the fore-part of the aorta, immediately below the renal arteries. Their origin is subject to considerable varieties. The two seldom arise at the same level, and the right is often a branch of the right renal artery. Sometimes one or both come off from the superior mesenteric. Occasionally there are two spermatic arteries on one or both sides, arising in the regular way. All these deviations are more frequently met with on the left than on the right side of the body. Each artery pursues a tortuous course downwards and outwards, passing behind the peritoneum obliquely across the psoas muscle and ureter, to which, as well as to the surrounding areolar tissue, it gives off several branches. The artery then enters the inguinal canal through the internal ring, and emerging at the external, passes down the cord, being surrounded in its course by the spermatic veins. The further distribution of the artery is thus correctly described by Sir A. Cooper: "When the artery reaches from one to three inches from the epididymis, varying in different subjects, it divides into two branches, which descend to the testicle on its inner side, opposite to that on which the epididymis is placed; one passing on the anterior and upper, the other to the posterior and lower part of the testis. From the anterior branch the vessels of the epididymis arise: first, one which passes to its caput; secondly, another to its body, and, thirdly, one to its cauda and the first convolutions of the vas deferens, communicating freely with the deferential artery. The spermatic artery, after giving off branches to the epididymis, enters the testis, by penetrating the outer layer of the tunica albuginea; and dividing upon its vascular layer, they form an arch by their junction at the lower part of the testis, from which numerous vessels pass upwards; and then descending, they supply the lobes of the tubuli seminiferi. Besides this lower arch, there is another passing in the direction of the rete, extremely convoluted in its course, and forming an anastomosis between the principal branches." The testis receives a further supply of blood from another vessel, the artery of the vas deferens, or posterior spermatic artery, which arises from one of the vesical arteries, branches of the internal iliac. This artery divides into two sets of branches, one set descending to the vesicula seminalis and to the termination of the vas deferens; the other, ascending upon the vas deferens, runs in a serpentine direction upon the coat of that vessel, passing through the whole length of the spermatic cord; and when it reaches the cauda epididymis, it divides into two sets of branches, one advancing to unite with the spermatic artery to supply the testis and epididymis, the other passing backwards to the tunica vaginalis and cremaster.

The spermatic veins spring in three sets from the testicle, one from the rete and tubuli, and another from the vascular layer of the tunica albuginea, and a third from the lower extremity of the vas deferens. The veins of the testicle pass in three courses into the beginning of the spermatic cord; two of these quit the back of the testicle, one at its anterior and upper part, and a second at its centre; and these, after passing from two or three inches, become united into one. The other column accompanies the vas deferens. There is also a large vein, just above the testicle, which crosses to join the three columns. The veins of the epididymis are one from the caput, another from its body; one from its cauda, and another from its junction with the vas deferens, besides some small branches; they terminate in the veins of the spermatic cord. The veins, after quitting the testicle, become extremely tortuous, and frequently divide and inosculate in the cord, forming a plexus termed *vasa pampiniformia.* These communications cease as the veins approach the ring, which they enter, and ascending along with the psoas muscle in company with the spermatic artery, unite to form a single vein which usually terminates on the right side in the vena cava inferior, and on the left, in the renal vein; though this is subject to some variety. The left spermatic veins pass under the sigmoid flexure of the colon. Many anatomists speak of the spermatic veins as being destitute of valves, which they assign as one of the reasons for the occurrence of varicocele. I have several times injected these veins with alcohol, and on laying them open have observed valves in the larger vessels, and I have also found injections thrown into the veins arrested by the valves. They are seldom seen, however, very near the testicle, or in the smaller veins forming the plexus; nor have I observed them within the abdomen.

Absorbents. — The absorbent vessels of the testicle are very numerous, and arise from every part of its internal structure and coats. They unite to form four or five trunks, which ascend along the cord, and traverse the inguinal canal, without communicating with the glands in the groin, but pass upwards in front of the psoas muscle, behind the peritoneum, and terminate in the lumbar glands on the side of the aorta.

Nerves. — The nerves of the testicle are derived chiefly from the renal plexus, but partly also from the superior mesenteric and aortic plexuses. These nerves descend in company with the spermatic artery to the cord, where, being joined by branches from the hypogastric plexus, which pass along the vas deferens, they form together the spermatic plexus, the branches of which are intermingled with the vessels of the cord, and ultimately terminate in the substance of the testicle. A few twigs from the external spermatic nerve may also be traced to the coverings of the gland.

The Testicle in the Fœtus, and its Passage into the Scrotum. — The testicles are first developed and situated in the abdomen. They originate from the lower part of the corpora Wolffiana, and may be detected at an early period of fœtal existence immediately below the kidneys on the forepart of the psoas muscles, to which they are attached by a reflexion of peritoneum. This membrane closely invests the testicles in the same manner as it covers the other abdominal viscera. The position of the testicle in the abdomen is nearly the same as it maintains after its passage into the scrotum. The epididymis, however, is relatively of a larger size than in the adult, being about one-third that of the body of the organ. Attached to each testicle whilst in the abdomen is a peculiar body, which was termed by Mr. Hunter, who first described it, the *gubernaculum,* as it was supposed to serve as a guide to the testicle in its passage. It is a soft solid projecting body of a conical form, which varies somewhat in shape and size at different periods of transition of the testes, becoming shorter and thicker as the gland approaches the abdominal ring. It is situated in front of the psoas muscle, to which it is connected by a reflexion of peritoneum. Its upper part is attached to the inferior extremity of the testicle, lower end of the epididymis, and commencement of the vas deferens. The lower part of this process passes out of the abdomen at the abdominal ring, and diminishing in substance and spreading, terminates in three processes, each of which has a distinct attachment. The central part and bulk of the gubernaculum is composed of a soft, transparent, gelatinous substance, which, on examination by the microscope, is found to consist of nucleated cells, the primitive areolar tissue : this central mass is surrounded by a layer of well-developed muscular fibres, which may be distinguished by the naked eye, and which can be very distinctly recognised in the microscope to be composed of striped elementary fibres. These muscular fibres, which may be traced the whole way from the ring to the testicle, are surrounded by a layer of the soft elements of the areolar tissue, similar to that composing the central mass ; and, in the same way as the testicle, the whole process, except at its posterior part, is invested with peritoneum. On carefully laying open the inguinal canal, and gently drawing up the gubernaculum, the muscular fibres may be traced to the three processes, which are attached as follows : the external and broadest is connected to Poupart's ligament in the inguinal canal; the middle forms a lengthened band which escapes at the external abdominal ring, and passes to the bottom of the scrotum, where it joins the dartos ; the internal takes the direction inwards, and has a firm attachment to the os pubis and sheath of the rectus muscle. Besides these, a number of muscular fibres are reflected from the internal oblique on the front of the gubernaculum. It thus appears, that the attachments of the muscle of the gubernaculum, and those of the cremaster in the adult are exactly similar. I have succeeded in tracing out the former before the testicle has moved from its original position, at different stages of the process of transition, and immediately after its completion ; and of the identity of the two muscles no doubt can be entertained. Carus was of opinion that the cremaster does not exist before the transition of the testicle; but that it is formed mechanically, by the testicle pushing before it the lower fibres of the internal oblique, so as to form the loops of this muscle.* This view which has been adopted by M. Jules Cloquet, and after him by many of the anatomists of this country, is erroneous and inaccurate.†

The vessels of the testicle in the fœtus

* Compartive Anatomy, by Gore, vol. 2. p. 347.

† Vide Obervations on the Structure of the Gubernaculum, and on the Descent of the Testis in the Fœtus, by the author, in Lond. Medical Gazette, April 10. 1841, or in the Lancet, of the same date.

arise from the nearest largest trunks, and enter the substance of the gland at its posterior part. The artery of the vas deferens, from which the gubernaculum is chiefly supplied, is nearly as large as the spermatic. The long course taken by the arteries and veins of the testicle when in the scrotum is thus explained by the original site of the organ, to which circumstance must also be ascribed the sharp turn upwards of the vas deferens from the epididymis, the two being continuous in a direct line, whilst the testicle is in the abdomen.

Fig. 636.

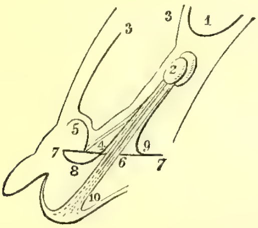

Diagram of the gubernaculum and testicle previous to its descent.

1, the kidney; 2, the testicle; 3, 3, the peritoneum; 4, vas deferens passing down into the pelvis by the side of the bladder; 5, the bladder; 6, the abdominal ring; 7, 7, Poupart's ligament; 8, pubic portion of the cremaster; 9, fibres of the cremaster arising from Poupart's ligament; 10, portion of the gubernaculum attached to the bottom of the scrotum.

Between the fifth and sixth month of fœtal existence, sometimes later, the testicle begins to move from its situation near the kidney towards the ring, which it usually reaches about the seventh month. During the eighth month it generally traverses the inguinal canal, and by the end of the ninth arrives at the bottom of the scrotum, in which situation it is commonly found at birth. The testicle, both during its passage to the ring and through the inguinal canal, carries along with it its original peritoneal coat, adhering by the reflexion of this membrane, during the whole of its course to the parts behind, in the same manner as whilst situated below the kidney. The testicle therefore does not pass directly and abruptly into a pouch prepared to receive it, but carries the peritoneum with it, continuing to be connected to the parts behind by the reflexion of the membrane, between the folds of which the vessels and nerves join the gland. In the passage of the testicle from the abdomen to the bottom of the scrotum, the gubernaculum, including its peritoneal investment and muscular fibres, undergoes the same change as that which takes place in certain of the *rodentia* at the access of the season of sexual excitement; the muscle of the testicle is gradually everted, until, when the transition is completed, it forms a muscular envelope external to the process of peritoneum, which surrounds the gland and front of the cord. As the testicle approaches the bottom of the scrotum, the gubernaculum diminishes in size, owing to a change in the disposition of its areolar elements; the muscular fibres, however, undergo little or no diminution, and are very distinct around the tunica vaginalis in the recently descended testicle. The mass composing the central part of the gubernaculum which is so soft, lax, and yielding, as in every way to facilitate these changes, becomes gradually diffused, and after the arrival of the testicle in the scrotum, contributes to form the loose areolar tissue which afterwards exists so abundantly in this part; the middle attachment of the gubernaculum, which may be traced to the dartos at the bottom of the scrotum, gradually wastes away and soon becomes indistinct, though slight traces of this process often remain to the latest period of life. Thus, after death, in dragging the testicle of an adult out of the scrotum by pulling the cord, the lower part of the gland, which is uncovered by serous membrane, is often found connected to the bottom of the scrotum by a band of firm and dense areolar tissue, which requires division with the scalpel. This band is the remains of the middle attachment of the gubernaculum. In cases in which the testicle has been retained in the groin, I have traced a cord of dense tissue from the gland to the lower part of the scrotum. After the arrival of the testicle in the scrotum, the peritoneum with which it is closely invested, its original envelope, becomes the inner layer of the tunica vaginalis; whilst the pouch around, which is continuous with it, forms the outer layer, or vaginal sac. Immediately after the arrival of the testicle in the scrotum, this bag communicates with the abdomen, and in quadrupeds continues to do so during life; but in the human subject it soon begins to close, and when the fœtus is ushered into the world, the abdominal orifice is often shut, and the whole canal from the ring to the upper part of the gland is, in general, completely obliterated in the course of the first month after birth. The obliteration is effected by an intimate union of the surfaces of the serous membrane. It sometimes does not take place at all*, or is delayed or only partially com-

Fig. 637.

* The communication constantly remains open in quadrupeds, the chimpanzee, according to Professor

pleted. Congenital hernia, or hydrocele is the result of a failure in this process; and other forms of hydrocele are occasioned by imperfect obliteration of the canal.

Much difference of opinion exists as to the immediate cause of the transition of the testicle. Hunter, Meckel, and others came to the conclusion that the muscular fibres of the cremaster are insufficient to bring the testicle further than the abdominal ring and complete the passage. They were not, however, acquainted with the attachment of this muscle to the pubis external to the ring, or it would be difficult to understand why Mr. Hunter, after arriving at the conviction that the cremaster passes to the testicle whilst in the abdomen, chiefly from analogy, was not induced by the same process of reasoning to conclude, that a muscle capable of changing the position of the testicle in brute animals, would be adequate to accomplish the same office in the human fœtus. The necessity for some active agent to effect this change in the latter would appear to be greater even than in the lower animals, since, in the usual position of the fœtus in utero, the passage of the testicle is contrary to gravitation,* and unaided by the movements of respiration. Now, when we consider the attachments and connections of this muscle in the fœtus; the perfect development of its fibres, as ascertained by microscopical examination; and the circumstance that there are no other means, no other motive powers, by which this change can be effected, or in any way promoted, I think there is no reason to doubt that the cremaster executes the same office in the human embryo, as that which it undoubtedly performs in certain brute animals at a particular season. The fibres proceeding from Poupart's ligament, and the obliquus internus, tend to guide the gland into the inguinal canal; those attached to the os pubis to draw it outside the abdominal ring; and the process extending to the bottom of the scrotum, to direct it to its final destination. As the process approaches completion, the muscular fibres which perform so important a part in it gradually become everted, and acquire the new functions of elevating, supporting, and compressing the gland.

The Functions of the Testicle. — The sperm or fluid secreted by the testicle has been considered in the article (SEMEN). On surveying the structure of this gland, we cannot fail to remark the great extent of secreting surface afforded by the numerous, long, and tortuous tubuli, and the length and complexity of the excretory duct through which the seminal fluid has to pass. The extent of this duct is, indeed, so remarkable, that many physiologists have been led to suppose that the semen is further elaborated or perfected in its passage through the convolutions constituting the epididymis. An examination of the spermatic fluid taken from the testicle and its duct both in man and in the lower animals, under all circumstances and at all periods, and the varying state of the discharge in cases of spermatic fistula, leave little room to doubt that secretion takes place actively only during the periods of sexual excitement, or under the influence of sexual feelings and desires. From birth to the period of puberty the testicles remain small, and grow but little in proportion to other parts; but as the body, on the arrival of puberty, becomes stamped with the characters of the male sex, they rapidly enlarge, their glandular structure becomes much more developed, and, being excited, these organs begin to exercise the office of secretion, no spermatozoa being found in them until this period arrives. The age at which the testicles thus become developed varies in different climates, and in different constitutions, and is influenced by the mode of life and circumstances in which the individual is placed. The inhabitants of warm climates reach the age of puberty earlier than those of cold countries. In this part of Europe the change takes place from the age of fourteen to seventeen years, according to circumstances. Unlike the inferior animals, the testicles in man are ready at all seasons to perform their office. The desires subside, and the secretion of semen becomes languid as life advances, though they seldom cease entirely till the age of sixty-five or seventy. Indeed, I have several times discovered spermatozoa in the testicles of men upwards of seventy years of age, and once in the testicle of a tailor who died at the age of eighty-seven. There are instances on record of persons retaining the procreative faculty to the age of one hundred years; but in these cases, as in the well-known instance of old Parr, the general bodily powers were also preserved in a very extraordinary degree.*

"To the use of the sexual organs for the continuance of his race man is prompted by a powerful instinctive desire, which he shares with the lower animals. This instinct is excited by sensations, and these may either originate in the sexual organs themselves or may be excited through the organs of special sensation. Thus in man it is most powerfully aroused by impressions conveyed through the sight or the touch: in many other animals, the auditory and olfactive organs communicate impressions which have an equal power; and it is not improbable that in certain morbidly excited states of feeling, the same may be the case in ourselves. That local impres-

Owen, being the only brute animal in which the tunica vaginalis forms a shut sac.

* For this reason I have departed from the usual custom of English anatomists, and avoided describing the change in the position of the testicle, as *the descent.*

* Old Parr, who lived to the great age of 152, was dissected by the celebrated Harvey, and it is stated, "Genitalibus erat integris, neque retructo pene neque extenuato, neque scroto distento ramice aquoso ut in decrepitis solet, testiculis etiam integris et magnis." Bettus de Ortu et Natura Sanguinis, p. 320.

sions have also very powerful effect in exciting sexual desire must have been within the experience of almost every one; the fact is most remarkable, however, in cases of satyriasis; which disease is generally found to be connected with some obvious cause of irritation of the generative system, such as pruritus, active congestion," &c.*

The part of the brain which is the seat of the sexual appetite is supposed by the phrenologists to be the cerebellum, between which and the genital organs a close sympathy is said to exist. The grounds for this assumption, and the objections which have been fairly urged against it by sound physiologists, have been stated in a preceding article. (Nervous System, Physiology of, vol. iii. p. 782. s.) No doubt, however, can be entertained that the mind is intimately connected with the procreative faculty, and that the brain controls and animates the desire for sexual enjoyment. An affection of the brain, or the mind, as sudden disgust, arrests the secretion of the testicles and extinguishes all desire as quickly and effectually as a strong mental impression stops the secretion of the gastric juice, and takes away all appetite for food. The influence of the brain on the reproductive function is well illustrated by the occasional effects of injuries of the head. Hildanus mentions the case of a man accused of impotency by his wife, who sued for a divorce. Nothing external was defective; but the man stated that eight years previously he had received a blow on his head by a stick. From that period, "confitebatur penem erigi non posse."† Dr. Fisher relates the case of a gentleman who, while looking out of the window of a railway carriage, which at that moment encountered a violent collision, received a blow on the head and neck, by which he was stunned. On the second day after the accident he complained of a numbness in his right arm, and experienced difficulty in passing his urine. In the course of two weeks he was able to leave his bed, and walk in the street; but his vision was defective. Between the fourth and fifth week after his injury he made the discovery that he had lost the desire and physical power for sexual intercourse, and that no amorous sentiment, or the approach of a female could excite it. Under appropriate treatment the bladder gradually recovered its power, and his vision became perfect; but the numbness of the right arm continued, and the generative functions remained partially impaired. His mental powers, particularly his memory of events, were also for a time seriously affected.‡ Dr. Gall mentions that at Vienna he was consulted by two officers who had become impotent in consequence of blows from fire-arms which had grazed the napes of their necks. One of the officers recovered his powers by degrees, married, and became the father of several children.*

When treating of Atrophy of these glands, I shall have occasion to mention cases in which the genital function has been permanently annihilated, and complete wasting of the testicles has resulted from injuries of the head. In respect to the mode in which these organs are called into action, they bear considerable analogy to the lachrymal, salivary, and mammary glands, in which secretion is excited both by the influence of the mind and by mechanical contact or local irritation of the extremity of the excretory duct, the glans penis holding the same relation to the testicle as the mucous membrane of the mouth does to the salivary glands, or as the nipple does to the mamma.

The influence of the testicles and brain upon each other appears, as has been already observed, to be reciprocal; for not only may desire be aroused by local irritation and exciting the testicles to secrete, but the passion itself never arises when these glands are removed before puberty and is extinguished by their extirpation afterwards. Nothing, indeed, illustrates more forcibly the intimate relation which the functions of the testicles bear to the mind and character of the individual, and the general organisation of the body, than the effects of castration. When it is performed in early life, the changes characteristic of puberty never ensue. There is a deficiency of the beard; the muscles do not acquire the manly tone and vigour; the areolar and adipose tissues abound; the voice retains the high and clear tones of infancy; and the mind remains deficient in energy and strength. When the testicles are removed after the period of puberty, the eunuch loses in part, though not entirely, his former masculine character. His beard grows less abundantly; his voice becomes shrill; and there is diminished energy and vigour in all his sentiments and actions. These changes in the constitution, as well as the loss of the sexual instinct which occur in men thus degraded, do not immediately succeed the removal of the testicles, but take place gradually; and there are well-attested cases in which desire has been experienced, and connection with emission accomplished many months after the loss of these organs. This shows that the passion is not solely dependent on the secretion of semen, though it invariably declines when the power of procreation becomes lost. The emissions in such cases are imperfect and fruitless, consisting merely of the secretions of the vesiculæ seminales and prostrate. The testicles not being parts essential to life, are subject to different laws from those which regulate the actions of the vital organs. Their functions may be suspended, or they may remain in abeyance for an indefinite period without injury to the glands or any material effect on the constitution. In persons of

* On the Functions of the Cerebellum, tr. by Combe, p. 46.

recluse and studious habits the functions of these organs often continue dormant for years. Like the mammæ in the unmarried female, though inactive, they remain sound and competent for secretion when duly excited and called upon to exercise their functions. It often happens that the passions are excited without an opportunity being afforded for their gratification. Under these circumstances the testicles become encumbered with secretion which would prove injurious to them were they not relieved by occasional nocturnal emission, or ejaculations of the semen under the influence of dreams during sleep, which appear to be a salutary provision to obviate the inconveniences which might result as well from ungratified desires as from an accumulation of semen in the ducts.

Envelopes of the testicle.—The *scrotum*, or pouch of integument containing the testicles, including the *dartos*, has already been described. (Article SCROTUM).

Superficial or external spermatic fascia. — Beneath the loose areolar tissue of the scrotum is situated a delicate layer of fascia, which is continuous with the superficial fascia of the lower part of the abdominal parietes, and, descending so as to form a sheath to the spermatic cord and an envelope to the testicle, becomes continuous behind with the superficial fascia of the perineum. This fascia is usually very thick and distinct in cases of large and old scrotal hernia.

Cremaster muscle — Directly beneath the superficial fascia is found the cremaster muscle (so named from *κρεμάω to suspend*), or, as it has been appropriately termed by Mr. Hunter, the *musculus testis*. (For description, vide, ABDOMEN, vol. i. p. 6.) The two attachments of this muscle, the external to Poupart's ligament, and the internal to the os pubis, correspond, as I have previously (p. 983.) shown, to those of the muscle of the gubernaculum, being indeed the same structure, with its relations altered. The actions of the cremaster, which, with a few exceptions, are involuntary, appear to be those of giving a tonic support to the testicles, retracting them to the abdominal rings, and compressing them during the sexual act. In some instances, in boys before the approach of puberty, this muscle has been capable of drawing the gland up into the inguinal canal. Persons are occasionally met with who possess a voluntary power over its actions in various degrees of perfection. Some are able to elevate the testicle on one side but not on the other, whilst others can retract both testicles to the abdominal rings, and retain them there at will. A very remarkable instance of the cremaster muscle being completely under the influence of volition is recorded by Mr. Hutchinson.*

Deep spermatic fascia. — The tunica vaginalis and spermatic cord are invested by a thin delicate fascia, which is situated beneath the cremaster muscle, and forms a common fibrous envelope to the testicle, and spermatic cord. It is attached to the back part of the gland. This membrane may be traced as a prolongation of the *fascia transversalis*, and is probably formed in the process of transition of the testicle from the abdomen to the scrotum.

The spermatic cord. — The parts composing the spermatic cord, are the vas deferens, the artery of the duct, the spermatic artery and veins, the lymphatic vessels, and the spermatic nerves. These parts are connected by loose areolar tissue. A fibro-cellular process, being the remains of the process of serous membrane originally connecting the tunica vaginalis with the peritoneum, may sometimes be perceived in the front part of the cord. The spermatic cord extends from the internal abdominal ring to the back part of the testicle. Its upper portion, therefore, lies in the inguinal canal. The coverings of the cord are the same as those of the testicle: viz., the integuments, superficial fascia, cremaster muscle, and deep spermatic fascia.

For COMPARATIVE ANATOMY, see the article ORGANS OF GENERATION.

ABNORMAL ANATOMY OF THE TESTICLE.— *Congenital imperfections and malformations.*— *Numerical excesses and defects.*— Cases of supernumerary testicles are mentioned in the writings of the old authors, and persons have been described with four or five of them, accompanied with a proportionate increase in the venereal appetite. Nearly all these cases are of a fabulous character. Such must be remarked of the case of *πεντόρχος*, or man with five testicles, mentioned by Schaarf*, and with that of a man with four testicles alluded to by Blegny.† Blasius, an old writer not unworthy of credit, has, however, given an account of the examination of a man, thirty years of age, and otherwise well formed, who had two testicles on the right side, of the same size and shape as that on the left, which is illustrated by a small engraved figure representing a distinct artery from the aorta, and vein from the vena cava proceeding to each of the two testicles on the right side.‡ This is the only case of supernumerary testicle recorded by the old authors, which has any semblance of authenticity. Neither Morgagni, Haller, nor Meckel met with a single example, and they questioned the existence of such a condition. Two cases have recently been recorded as examples of triple testicle, but they were not verified by examination after death. One is related by Blümener, an army surgeon, in Rust's Magazin für die Gesammte Heilkunde for 1824: the other by Dr. Macann, a British surgeon.§ An epiplocele, a fatty or fibrous tumour in the scrotum, or an encysted hydrocele of the cord,

§ Provincial Medical Journal, Nov. 5. 1842, p. 113.

might readily be mistaken for an additional testicle. Morgagni mentions that he was once deceived by a portion of omentum. In the pathological collection at St. Thomas's Hospital is preserved the testicle of the eccentric Dr. Monsey, who appeared during life to be supplied with three of these glands. The supposed additional testicle consists of an indurated fibrous tumour attached apparently to the tunica vaginalis.

Many instances of *monorchides*, or persons having only a single testicle are also mentioned by the old authors; but as the data are very imperfect, and as little was known respecting the transition of the testicle at the time these cases were recorded, they must be viewed with great suspicion. They were most probably cases in which one of the glands was either retained within the abdomen, or, from some cause had been completely atrophied. I know no satisfactory reason why a deficiency of one or both testicles should not occasionally occur without any other malformation; but they are anomalies of which there are few authentic examples in the annals of medical science. Mr. Paget has published the particulars of a case in which he believes one testicle was deficient at birth.* No account of the man is attached to the particulars of the dissection, and it is open to question whether the deficiency of the gland was not the result of atrophy. Dr. Fisher, of Boston †, has recorded a more satisfactory example of absence of both testicles. The deficiency was remarked from birth, and the subject of the malformation was regarded as a natural eunuch, and died at the age of forty-five.

Mr. Thurnham has published an account of the dissection of an infant who died at the age of four months. In addition to an atrophied condition of the right kidney, and a remarkable malformation of the ureters, it was found that neither of the testicles had descended. The right lay in the abdominal cavity, just above the inguinal canal. On the left side no testicle would appear to have been formed; the spermatic vessels on this side terminated in a little mass of fat; the vas deferens, however, was present, and was apparently as well developed as that of the perfect testicle.‡ A case of monstrosity is related by Dr. Friese in Casper's Wochenschrift.§ The child lived only half an hour: in addition to the absence of the external genital organs, there were neither testes, vasa deferentia, nor vesiculæ seminales. Cases, however, in which the whole of the genital apparatus is deficient or irregularly formed, do not come within the scope of this article. Geoffroy St. Hilaire has recorded a remarkable, and so far as I know, unique case of union of the testicles in the abdomen. ||

|| Hist. des Anomal. de l'Organ. t. i. p. 542.

Deficiencies and imperfections of the vas deferens. — In Mr. Paget's case of supposed absence of the testicle it is stated, that the vas deferens terminated nearly opposite the external ring in a rounded cul-de-sac; and in Dr. Fisher's case of deficiency of both testicles, that the vasa deferentia, though properly formed and nearly of natural size, terminated in cul-de-sacs at the end of the cord. In the museum of St. Bartholomew's Hospital, there is a preparation taken from a man fifty years of age, who died of strangulated hernia. A piece of intestine was strictured by a band of adhesion connected with the mesentery, and the testicle was detained in the upper opening of the ring. On dissection of the parts, the vas deferens was found to terminate near the testicle in a cul-de-sac. The gland was very small, and its structure appeared granular like the undeveloped testicle of a youth. There was no trace of the epididymis. Mr. Hunter in dissecting a male subject found the vasa deferentia not only deficient near the testicles, but terminating below in a single irregularly formed vesicula seminalis, and having no communication with the urethra.* There are a few other cases on record, in which the vas deferens has been defective at the extremity which joins the ejaculatory canal. Thus, Tenon, in the dissection of an infant affected with extraversion of the bladder, found that the vasa deferentia terminated separately at the bottom of the pelvis, in two white tubercles: the scrotum, testes, and vesiculæ seminales were in a natural state.† But besides these imperfections at its two extremities, this duct has been found wanting throughout nearly its whole extent. Brugnoni mentions, that in dissecting the parts of generation in a robust man, from twenty-six to twenty-seven years of age, he found the right epididymis almost entirely absent, the only part remaining being the head, which formed nodules filled with semen. The rest of the epididymis and the vas deferens were wanting, without any mark of disease. The testicle was perfectly sound, and nearly of the same size as the left one. On examining the corresponding vesicula seminalis he found at its anterior extremity a portion of the canal of the vas deferens about an inch in length, and properly formed. The vesicula seminalis itself was flaccid and quite empty; whilst the left was full of semen. He remarks, that although this vicious conformation was according to all appearances congenital, nevertheless the vesicula seminalis and ejaculatory canal had preserved their natural cavities.‡ In a case related by Bosscha, the left vas deferens of a robust man terminated in a blind extremity near the testicle, the rest of the canal being wanting. There was the rudiment of a left vesicula seminalis in the

form of a blindly-ending canal running tortuously in the shape of the letter S. The left testicle was sound.*

Mr. Paget has happily explained the origin of these several defects in the vas deferens, by reference to the mode of development of the special organs of generation. He observes†, after Müller and Valentin, that, in the normal course of human development the proper genital organs are in either sex developed in two distinct pieces : namely, the part for the formation of the generative substance, the testicle or ovary, and the part for the conveyance of that substance out of the body, the seminal duct or ovi-duct. The testicle or ovary as the case may be, (and in their earliest periods they cannot be distinguished), is formed on the inner concave side of the corpus Wolffianum, and the seminal or ovi-duct, which is originally an isolated tube closed at both extremities, passes along the outer border of that body from the level of the formative organ above to the cloaca or common sinus of the urinary, genital, and digestive systems below. The perfection of development is attained only by the conducting tube acquiring its just connections at once with the formative organ, and, through the medium of the cloaca, with the exterior of the body. The sexual character is first established, when, in the male, the formative and conducting organs become connected by the development of intermediate tubes which constitute the epididymis ; or when in the female, a simple aperture is formed at the upper extremity of the conducting tube, and is placed closely adjacent to the formative organ. In both sexes alike, the lower extremities of the conducting tubes first open into the common cloaca, and subsequently, when that cavity is partitioned into bladder and rectum, or bladder, vagina, and rectum, they acquire in each their just connections, and become in the male the perfect vasa deferentia, and in the female the Fallopian tubes and uterus.

The inquiry is not without interest, what influence have these deficiencies and imperfections in the vas deferens on the evolution and subsequent condition of the testicle ? In the case of the adult which occurred at St. Bartholomew's Hospital, the testicle was small, and its structure appeared granular, like the undeveloped testicle of a youth, but as it had not descended into the scrotum, and was combined with hernia, there may have been other causes impeding its due evolution. In Mr. Hunter's case, the testicles which were in the scrotum were very sound. In the case of the man related by Brugnone, the testicle on the side corresponding to the defective vas deferens was perfectly sound, and nearly of the same size as the other. So also in Bosscha's case, it is stated, that the testicle was sound. Although either of these defects in the vas deferens renders the gland an useless organ, and if it occurred on both sides of the body, would necessarily cause impotency, these cases, nevertheless, tend to shew that the absence or imperfection of the excretory duct does not prevent the development of the testicle at the proper period, and has no direct influence in causing it to waste; and these inferences are fully confirmed by experiments on animals, performed by Sir A. Cooper and by myself.* These cases and experiments show, then, that the testicles may be properly developed, though a physical obstacle to the elimination of their secretion is present from birth ; and that so long as the testicles exist entire, though to no purpose, the individual acquires and preserves all the marks of the male sex ; the secretory organ alone appearing to be that upon which the sexual characters depend. The engorgement of the seminal ducts with sperm is liable, it is true, to cause inflammation of the testicle, which may end in atrophy, but this is only a secondary and occasional effect of the interruption in the excretory duct.

Imperfect transition. — It occasionally happens that at birth one or both testicles have not passed into the scrotum, being detained either in the abdomen near the groin, in the inguinal canal, or in the groin, just outside the external ring. In a table of one hundred and three male infants, examined by Wrisberg at the time of birth, it appears that seventy-three had both testicles in the scrotum ; in twenty-one, one or both were in the groin. Of these, five had both, seven the right, and nine the left in the groin; in twelve, four had both, three the right, five the left, only in the abdomen.† According to this table, the imperfection occurs rather more frequently on the left side than on the right, in the proportion of seven to five. In twenty-five cases examined at different ages, varying from five to sixty, — sixteen of which came under my own observation, the remainder being taken from the recorded experience of others, — in thirteen the imperfection was on the right side, and in twelve on the left. Dr. Marshall states, that in the examination of 10,800 recruits, he had found five in whom the right, and six in whom the left testicle was not apparent. In two of these cases there was inguinal hernia on the side where the testicle had not descended.‡ He met with but one instance in which both testicles had not appeared.§ The testicle sometimes remains permanently fixed in the situation in which it is placed at birth || ; but in some instances the passage, though delayed, is completed at some period previous to puberty, and often within a few weeks after birth. Mr. Hunter was of opinion that this completion most frequently

|| Persons whose testicles had not made their appearance were called κρυψόρχιδες, or *testicondi*, by the ancients.

happens between the years of two and ten.* Of the twelve cases mentioned by Wrisberg, in which one or both testicles were retained in the abdomen, in one the descent took place the day of birth, in three on the day after, in three others on the third day, in two instances on the fifth day, and in one on the twenty-first day: in the other cases, the testicles had not appeared at the fourth or fifth week after parturition.† My own observations lead me to believe, that if the passage does not take place within a twelvemonth after birth, it is rarely fully and perfectly completed afterwards, without being accompanied with rupture. For the causes which operate at this late period tend as much to promote the formation of hernia as the transition of the testicle. In cases where the testicle makes no appearance before puberty, uneasiness is often experienced at that period, owing to the enlargement of the gland being restrained by the rings and parts composing the inguinal canal. At the same time also, it is often protruded outside the external ring by the movements of the abdomen in respiration.

The causes of a failure in the transition of the testicle have not been much investigated, and as considerable doubt has long prevailed respecting the mode and agency by which this change is effected, no satisfactory explanation could be expected of the circumstances interrupting or preventing it. When we reflect on the nature of that process, as my researches have led me to describe it, it is clear, that there must not only be a perfect adaptation of parts, a due relation between the body displaced and the structures which it traverses, but also corresponding power in the agent by which it is accomplished. There are few muscles in the human body whose development in different individuals varies in a greater degree than that of the cremaster. And if such be the case after birth, it is not unreasonable to presume that similar differences exist in the fœtus before the gland changes its position, and that a failure in the process may be the result of deficient power in the *musculus testis* to accomplish the passage. It is not improbable that this muscle is sometimes paralysed, and that the faulty transition is owing to a want of a due supply of the nervous energy, which we know is often denied to other muscles during fœtal existence, and is the cause of deformities in the feet and other parts, with which infants are often ushered into the world. I think, indeed, we may fairly enumerate paralysis and defective development of the cremaster amongst the presumed causes of the imperfect transition of the testicle. Peritonitis occasionally attacks the fœtus in utero ‡, and produces adhesions between the various abdominal viscera. It is well known that in congenital hernia the testicle is frequently united to a portion of intestine or omentum, and that the formation of these adhesions previous to the transition of the testicle is sometimes the cause of the displacement, the viscera being drawn, together with the gland, into the scrotum. Many facts seem to show that similar adhesions are, on the other hand, an occasional cause of the temporary and permanent retention of the testicle, the cremaster being insufficient to overcome this obstacle to its passage.

In the examination of a man, age sixty, I found the right testicle just external to the abdominal ring; it was small in size, and closely adherent to a portion of omentum. A young man was under my care for many months, on account of an imperfect transition of the testicle on the left side. The gland moved backwards and forwards through the external abdominal ring. By pressure above, it could be forced down sufficiently to admit of being examined. This testicle was much smaller than the right, which was in the scrotum, and I could distinctly make out a portion of intestine closely adherent, which accompanied the organ in all its movements. It is probable that the smallness of the opening in the internal abdominal ring is sometimes a cause of the detention of the testicle, especially in those cases in which the organ is retained within the inguinal canal. Mr. Wilson, an accurate anatomist, was of this opinion*, which is supported by the fact, that the testicle is oftener found in the groin than in the cavity of the abdomen. M. Delasiauve mentions a case, in which, he states, the organ was retained by the border of the outer column of the ring.† Mr. Hunter was inclined to suspect that the fault originates in the testicles themselves. It is difficult to understand how this can be, for as the gland is passive in this process, it can offer no obstacle, unless it grows too large to pass the opening in the abdominal parietes; whereas, it is admitted that the gland when retained is usually below the natural size. Nor does it appear, that the interruption is owing to any want of proper length in the vas deferens, for in a case of imperfect transition in a boy, whose body I examined, I particularly noticed that this duct was so long as to be doubled on itself, and tortuous, a circumstance which has been remarked in other cases by Mr. Mayo‡, Rosenmerhel§, and others. It may be concluded then, that the causes of a failure in the passage of the testicle are various; that this imperfection may result from want of power, or paralysis of the cremaster muscle; from adhesions retaining the gland within the abdomen; and from a contracted state of the opening of the external abdominal ring.

Mr. Hunter states, that when one or both testicles remain through life in the belly, he believes that they are exceedingly imperfect,

§ Ueber die Radicalcur des in der Weiche liegenden Testikels.

and probably incapable of performing their natural functions; and that this imperfection prevents the disposition for descent taking place. That they are more defective even than those which are late in passing to the scrotum, he infers from the circumstance, that in quadrupeds, the testicle that has reached the scrotum is considerably larger than the one which remains in the abdomen. Mr. Hunter had seen only one case in the human subject where both testicles continued in the abdomen, but this proved an exception to the above observation, since we are led to conclude that they were perfectly formed, as the person had all the powers and passions of a man.* Professor Owen in commenting upon these observations, states, "It seems remarkable that with this experience Mr. Hunter should have formed from inconclusive analogy, and promulgated, an opinion tending to occasion so much unhappiness as that which attributes exceeding imperfection and probable incapacity of performing their natural functions to testes which in the human subject are retained within the abdomen. That there is nothing in such a situation which necessarily tends to impair their efficiency is evident, from the number of animals in which they constantly form part of the abdominal viscera; and in those in which the testes naturally pass into a scrotum, their continuance in the abdomen, according to our author's own observation, is accompanied only with a difference of size or shape; now we may readily suppose that this may influence the quantity, but not necessarily the quality, of the secretion." There are very few accounts on record of the dissection of undescended testicles. In a case, in which M. Cloquet found the left testicle situated within the abdomen, the gland was well formed, and of the same size as the right, which had descended into the scrotum. The parts taken from an apprentice of Sir A. Cooper, who unfortunately committed suicide in consequence of the infirmity, are preserved in the Museum of Guy's Hospital. I have examined the preparation; and the testicles, which are both within the abdomen, close to the internal ring, appear to be nearly, if not quite, the natural size, and it is stated that the ducts contained semen. In a lad, aged nineteen, whose left testicle was found, by Dr. Bright, within the abdomen, near the brim of the pelvis, the gland was considerably smaller than natural, but the ducts and secreting structure were quite perfect.† These are the only cases of testicles situated within the abdomen in which we have any account of the anatomical condition of the gland. In addition to the evidence they afford of the capability of testicles thus placed to exercise their functions, may be adduced the case of Mr. Hunter, just alluded to, in which a person, both of whose testicles continued in the abdomen, had all the powers and passions of a man; and a case recorded by Mr. Poland, of a man so formed, who was aged twenty-nine. He had all the signs of virility, had married twice, and was the father of two children.* On the other hand, Mr. Wilson mentions the case of a young man, twenty-five years of age, whose testicles never descended. He had some beard, and not an unmanly appearance; but although an imprudent, and in some things a dissipated person, he had never shown the least desire for women, or disposition for sexual intercourse.† John West, a lad, aged sixteen, died in the London Hospital, in a state of universal anasarca. There was no appearance of beard, and only a few hairs were scattered over the pubes. My attention was particularly directed to the state of the genital organs, by observing that the scrotum, which was greatly distended with serous effusion, was not fully developed on the right side. I found the right testicle within the abdomen, about an inch and a half above the internal ring. It was very small, not larger than that of a child two years of age; and on cutting into it, the gland presented the granular appearance usually remarked at that early period.

* Works by Palmer, vol. iv. p. 18.

† Hospital Reports, vol. ii. p. 258.

Passage of the Testicle into the Perineum. — Mr. Hunter first observed that the testicle in changing its situation does not always preserve a proper course towards the scrotum, there being instances of its taking another direction and passing into the perineum. How this is brought about, he remarks, it is difficult to say: it may possibly be occasioned by something unusual in the construction of the scrotum, or more probably, by a peculiarity in that of the perineum itself. For it is not easy to imagine how the testicle could make its way to the parts about the perineum, if these were in a perfectly natural state. He met with two instances of this imperfection. Many years ago a little boy, one of whose testicles had thus deviated from its proper course was brought to the London Hospital. The gland was lodged in the perineum at the root of the scrotum. M. Ricord met with this singular anomaly in two instances. M. Vidal (de Cassis) observed it in two brothers: their father was exempt from it. The testicle abnormally placed was smaller than the other.‡ The irregularity is exceedingly rare, and the above cases are all with which I am acquainted.

Passage of the Testicle through the Crural Ring. — M. Vidal relates the case of a man, one of whose testicles, instead of passing out of the abdomen at the inguinal canal, made its exit at the crural ring. The organ was mounted upon the abdomen like a crural hernia. A portion of intestine traversed the inguinal canal, forming a rupture on that side.§ I know of only one other instance of this

* Guy's Hospital Reports. Second series, vol. i. pp. 162, 163.

† Lectures on the Urinary and Genital Organs, p. 408.

‡ Traité de Pathologie externe, t. v. p. 432. 2eme, edit.

§ Ibid p. 431.

anomaly, which is reported by Eckardt. In this case, the testicle passed out at first through the inguinal canal, but having been returned by the patient into the abdomen, it subsequently escaped at the femoral ring.*

Inversion of the Testicle. — It sometimes happens that the position of the testicle in the scrotum is reversed, so that the free surface presents posteriorly, and the epididymis is attached to the anterior part of the gland, instead of to the posterior. The first case that I met with was that of a man who had a swelling of the right testicle, which puzzled his medical attendant. On examination I found this to be the epididymis thickened from chronic inflammation. I was able clearly to trace the vas deferens proceeding to it along the front of the scrotum. The body of the testicle was unaffected, and its posterior edge was quite smooth and regular. The disposition of the left testicle was normal. On visiting the Hôpital de Midi in Paris, in April, 1849, M. Ricord showed me a case of epididymitis on the left side, in which the gland was thus inverted. He informed me that he had often met with this arrangement. I have since had two patients under my care, one of whose testicles was thus inverted. One was a lad in the London Hospital affected with epididymitis. The other was a gentleman who consulted me for chronic orchitis confined to the body of the testicle. The epididymis being unaffected, the inversion was less perceptible than in the three preceding cases. M. Maissonneuve, in a thesis published in Paris in 1835, I believe first called attention to this irregular disposition, which he states that he had met with many times upon the dead body, and upon the living, and he mentions what I remarked myself in the four cases just noticed, that the inversion was confined to one side. Surgeons should bear in mind the liability to this disposition of the gland in making their diagnosis of the diseases affecting it.

Atrophy of the Testicle. — The testicles, like other organs formed for the exercise of temporary functions, do not arrive at a perfect state of development until a certain period of life, after which their activity ceases, and they become gradually and imperceptibly diminished. Thus we find that in early life they are small in proportion to the size of the body as compared with their condition at puberty, and that as old age advances and the generative functions cease to be called into action, they undergo a diminution in size, their vessels grow less, the seminiferous tubes become small and contracted, and partially obliterated. In the lower animals these changes are far more remarkable than in man, for as the functions of the testicle are exerted only at stated periods of the year, as the rutting or copulating season advances these organs rapidly increase in bulk, and in its decline undergo a proportionate degree of wasting. In man, it sometimes happens that the testicles do not acquire their proper size at the usual period, their development being from some cause or other arrested ; and also, after the organs have arrived at their full and perfect growth, that occasionally one or both suffer a premature decay. Under the head then of Atrophy of the Testicle I shall consider: 1. *Arrest of Development;* and 2. *Wasting.*

Arrest of Development. — If the congenital lesions to which the testicle is liable had not been previously treated of, the cases of absence of the organ already described, might be correctly referred to the present head, as the deficiency in these cases was no doubt the result of an arrest in the early development of the organ. But the cases that I am now about to consider are those in which the subsequent evolution which the testicles undergo at puberty is delayed beyond the usual period, or never takes place at all. Mr. Wilson relates a curious instance of his having been consulted by a gentleman, twenty-six years of age, on the propriety of entering the marriage state, whose penis and testicles very little exceeded in size those of a boy of eight years of age. He had never felt the desire for sexual intercourse until he became acquainted with his intended wife; since that period he had experienced repeated erections, attended with nocturnal emissions. He married, became the father of a family ; and these parts, which at six and twenty years of age were so much smaller than usual, at twenty-eight had increased nearly to the usual size of those of an adult man.* Mr. Wilson mentions this singular case, as it will admit of questions whether the parts alluded to became properly formed as to size, and possessed of the power of secretion, in consequence of being, although so late in life, influenced by the passions excited by attachment to a particular female ; or whether the enlargement and proper action of the parts beginning, occasioned such passion first to exist. He thinks the probability in favour of the former supposition, in which opinion I certainly concur. Lallemand mentions having seen a man about thirty years of age, extremely fat, and without a beard or hair on the pubes, whose penis and testicle appeared to belong to a child of from seven to eight years: he had never experienced erections or venereal desires.† A young man died in the London Hospital of disease of the heart. He was seventeen years and nine months old : the body measured five feet five inches in height, and was plump and well formed. There was no appearance of beard, or whiskers, or of hair on the pubes. The penis and testicles were very small, not larger than they are usually found in boys of three or four years of age. The testicles were about equal in size, and one of them weighed only two scruples and one grain. Both organs were normal in structure, appearing like the glands in early life, when the tubular structure

* Loder's Journal für die Chirurg. ii. Bd. 1 Stff. s. 187.

* Lectures on the Urinary and Genital Organs, p. 424.

† Des Pertes Séminales Involontaires, t. ii. p. 380.

is very indistinctly developed. No spermatozoa could be detected. These were clearly instances of arrest of development of the testicles. As these organs are chiefly excited to action by an operation of the mind, it is easy to understand that they may sometimes remain undeveloped owing to defective organisation of the brain, an absence of sexual desires being invariably remarked in these cases. Cases of wasting of the testicles after injuries of the head, and the frequent absence of the venereal appetite in cretins and idiots, tend to strengthen this opinion. The following are marked examples of defective development of the sexual organs, accompanied with imperfection of the brain. An idiot, aged nineteen, subject to epileptic fits, died of typhus fever in the Hackney union. The youth was of short stature, and the form of the body was not indicative of either sex, but the contour was rounded as in the female. There was no appearance of hair about the face or pubes. The abdomen and other parts were covered with a thick layer of fat. The penis and scrotum were remarkably small, not larger than they are usually found in a child two or three years of age. Both testicles were in the scrotum, but they were of very diminutive size ; the right weighed less than a drachm, and the left not more than twenty three grains. The right gland had descended a very little way below the abdominal ring. The glandular structure and epididymis of both testicles were indistinct, and the vasa deferentia also extremely small. Nothing remarkable was observed in the structure of the brain. Mr. Hovell, the surgeon of the union, also showed me another inmate of the same workhouse, a lad aged nineteen, and of weak mind, whose penis and testicles did not exceed in size those of a boy seven or eight years of age, and who had only a few scattered hairs on the pubes. In the museum at Fort Pitt, Chatham, are preserved two undeveloped testicles about the size of those of a child six months old, but healthy in structure, which were taken from a lunatic 58 years of age. His penis was small and he had never experienced any inclination for sexual intercourse.

Wasting. — In investigating the alterations in the nutritive condition of the testicle, it is very desirable to fix, if possible, some standard by which they may be estimated. The size of the gland is neither uniform nor conveniently appreciated. Its weight, likewise, varies so much in different persons and in the same individual at different periods, according as it has lately exercised its functions or remained inactive, and as it is full of semen or empty, that it is scarcely possible to determine on any accurate standard of this kind. (See p. 976.)

I should consider the testicle of an adult weighing less than three drachms as in a state of atrophy. A testicle in an advaced state of wasting, not arising from disease of the gland, usually preserves its shape, but feels soft, having lost its elasticity and firmness. Its texture is pale and exhibits few blood-vessels, the tubuli and septa dividing the lobes are indistinct, and the former cannot be so readily drawn out into shreds as before. The epididymis does not usually waste so soon nor in the same degree as the body of the testicle. It sometimes however, loses its characteristic appearance, and I have even found it reduced to a few fibrous threads. The fluid pressed out of the wasted testicle and epididymis is entirely destitute of spermatic granules and spermatozoa. In many instances adipose tissue is deposited behind the tunica vaginalis, and encroaches on the epididymis and posterior part of the testicle. Fatty matter is also found in the glandular substance of atrophied testicles, as in one taken from a man aged forty-six, who died of dropy consequent on disease of the kidneys, which was wasted to one fifth its natural size. In addition to the presence of adipose tissue beneath the visceral portion of the tunica vaginalis, I recognised a quantity of yellow matter irregularly disposed amongst the wasted tubuli. This matter on examination in the microscope, proved to be oil globules, and readily dissolved on the application of ether. The structures composing the spermatic cord undergo a corresponding diminution ; the cremaster muscle disappears, the nerves shrink, and the vessels are reduced in size and number. The vas deferens, though small, can generally be injected with mercury as far as the commencement of the epididymis. A testicle, atrophied from disease, is not only of diminished size and weight, but is altered in shape, being uneven and irregular, and sometimes of an elongated form. The surfaces of the tunica vaginalis are adherent and its cavity is partly or entirely obliterated. There is no, or very little, trace of the proper glandular structure, the organ being converted into fibrous tissue of a firm texture. It loses its peculiar sensibility to pressure, but is sometimes the seat of morbid sensibility.

All those causes which produce decay in other parts likewise occasion wasting of the testicle. Thus an impeded circulation, pressure, want of exercise, and loss of nervous influence, have been noticed as causes of atrophy of this gland. To these must be added certain causes which specially affect the testicle. The following case, related by Mr. Wardrop, is a good example of atrophy from defective nutrition. A person, both of whose testicles were completely absorbed, nothing being felt in the scrotum but a loose vaginal coat, died of an aneurism of the aorta, formed at the origin of the spermatic arteries, both of which were obliterated.* A ligature on the spermatic artery is sufficient to cause a total decay of the testicle, which induced the celebrated Harvey † to propose its ap-

* Note to his edition of Baillie's works, vol. ii. p. 315.

† Anatomical Exercitations concerning the Generation of Living Creatures. Lond. 1653, pp. 113, 114.

plication for the removal of a certain form of sarcocele; a suggestion, the credit of which has been improperly assumed in recent years by C. J. Maunoir, of Geneva. The influence of pressure in causing partial atrophy of the testicle, is somtimes remarked in old cases of hydrocele and hœmatocele, in which the gland has been long subjected to compression from the retained fluid.

It has been said that the testicles waste in those persons who strictly adhere to their monastic vows, but I am not aware that there is sufficient authority for this remark. In persons who marry, after many years of abstinence from sexual intercourse, the testicles undergo a certain degree of enlargement. It is a great error to suppose that sexual connection in early life is essential for the preservation of these organs. In cases of enlargement of the prostate the ejaculatory canals sometimes become completely obstructed. Under these circumstances, the semen secreted under excitement having no means of escape, encumbers the testicles for a time, but afterwards becomes absorbed, and it is said that atrophy of these glands sometimes follows; but I have never observed any instance of wasting of the organs from this cause. As examples of atrophy of the testicles from loss of nervous influence, may be adduced cases of paraplegia, in which these organs have been known to waste. Portal mentions the case of a robust man, aged thirty-five, who was attacked with painter's colic, attended with great debility of the lower extremities. The testicles diminished considerably; and although he afterwards recovered from the paralysis of his limbs, these glands always remained wasted; and the man was incapable of the act of generation.* In the xxth volume of the "Medical and Physical Journal," there is an account of a case of recovery after fracture, with partial dislocation of the first and second lumbar vertebræ, followed by paraplegia, in which, three years afterwards, the testicles were found entirely obliterated. It has been stated that the testicles sometimes waste from injuries, or from compression of the spine at the origin of the spermatic nerves. In a man who had received a blow on the lumbar region, the testicles gradually wasted away.†

The most common cause of atrophy of the the testicle is the disturbance in its organisation consequent upon inflammation. As the inflammatory process ceases, the enlarged gland not only becomes reduced to its original size, but it sometimes slowly but steadily diminishes, till at length very little vestige of it remains Mr. Hunter has related three cases in which the testicle decayed in this way.‡ I have met with several instances of atrophy arising from this cause, and there are few surgeons of experience who have not witnessed cases of the kind. Wasting of the testicle has been observed to occur after an attack of orchitis in mumps, arising as it is supposed from the translation of inflammation from the parotid to the testicle. Two cases of cynanche parotidea in the adult, in which atrophy took place in the gland chiefly affected, are related by Dr. R. Hamilton.* I have witnessed one case, in which the patient attributed the loss of the gland to an attack of mumps in his infancy. Wasting is more liable to occur after inflammation of the body of the gland than after consecutive inflammation in which the epididymis is the part chiefly affected. One or both testicles have been found to waste in persons who have indulged too much in sexual intercourse or been addicted to onanism. Baron Larrey met with several cases of atrophy from excessive venery and abuse of strong drinks amongst the soldiers of the Imperial Guard.† Sir B. Brodie has recorded two cases in which wasting was occasioned by over-excitement; in one from onanism, in the other from sexual intercourse.‡ I have also witnessed an instance of total atrophy of the left testicle in a person addicted to excessive masturbation. In this case, and probably in the others just quoted, the wasting was preceded by an attack of inflammation induced by inordinate excitement.

It is a common belief that wasting of the testicle is liable to be induced by the long-continued use of iodine. I have not met with any instance of it, and there are few cases in which the evidence is such as to render it at all clear that the decay of the gland was really occasioned by the remedy. M. Cullerier has published the case of a young man who took from twenty-five to thirty drops of the tincture of iodine for a period of three months for the cure of an obstinate gonorrhæa. This was followed by a state of impotency and partial wasting of the testicles, which lasted a twelvemonth, and the organs never regained their former size and vigour. M. Cullerier mentions another case of temporary loss of virile power occurring from the use of the iodine of iron.§ I feel convinced, however, that if iodine produces wasting of the testicle at all, it does so so rarely, that the liability cannot be regarded as any objection to the free and long-continued use of this valuable remedy. Atrophy of the testicle has been remarked in elephantiasis of the Greeks, a disease in which tubercles are developed in various parts of the skin. Dr. Adams, in an account of the cases of that disease observed in Maderia, states that all those who were attacked with it before the age of puberty never acquired the distinguishing marks of that change in the constitution, and their testicles diminished in size, and that in those affected later in life the testicles became

§ Mémoires de la Société de Chirurgie de Paris, t. i.

atrophied, and they lost the power of procreation.* Mr. Peacock also noticed a wasting of the testicles in several cases of elephantiasis in the Leper Hospital of Colombo, in Ceylon.† A similar condition of these glands was remarked in a case of this disease, so rare in this country, narrated by Mr. Lawrence ‡, and also in another case at the London Hospital, which I recorded many years ago.§ In a confirmed case however of this disease, in a boy aged thirteen, who was under my care in the year 1849, there was no diminution in the size of these glands. Wasting of the testicles is liable to occur after injuries of the head.

Some years ago I saw a man who had met with an injury of this description, which had been followed by wasting of the testicles, and the development of tumours on each side of the chest, resembling mammæ. He was about fifty-nine years of age, a married man, and the father of several children. He had belonged to the legion in the Queen of Spain's service. About two years and a half previously, in an attempt to jump over a trench, he fell backwards and injured the posterior part of his head. Whilst on the ground he received a bayonet wound on the side, and a sabre cut on the forehead. He recovered from these injuries and returned to England. Since the accident he had completely lost his virility. He had no desire for sexual connection; his penis had dwindled in size; his right testicle had gradually wasted, and was no larger than a horse bean, and the left gland was also a good deal diminished in bulk. The skull at the occiput seemed somewhat flattened. Baron Larrey records the case of a man who was wounded in the back of the neck by a musket ball which grazed the inferior occipital protuberance. He recovered from the injury, but the testicles were reduced to a state of atrophy, and the penis shrunk and remained inactive. He also relates the case of a man of strong constitution and vigorous passions who received a sabre wound which cut off all the convex projecting part of the occipital bone, and exposed the dura mater. The patient lost the senses of sight and hearing on the right side, and his testicles sensibly diminished, and in fifteen days were reduced, especially the left, to the size of a bean.‖ Lallemand had under his care a man thirty years of age, who, in the expedition to Algiers had received a sabre wound at the nape of the neck. His testicles were wasted, and venereal desire as well as erections had entirely ceased.¶ We cannot doubt that in these cases the loss of sexual desire, and the wasting of the testicles were the direct results of the injury to the brain, and they go far to prove the essential dependence of the functions of these glands upon the cerebral organ. The physiologist cannot fail to notice the rapidity with which the atrophy is stated in some of the cases to have succeeded the injury and the extent to which it proceeded. The withering of the testicles, was, indeed, so remarkable, that it can only be attributed to the sudden and complete extinction of the sexual instinct resident in the brain, and (if I may so express myself) to the immediate impression on the system of the future uselessness of these organs. In old age and in lingering diseases the decay of the testicles is extremely slow and gradual, and is never carried to the extent observed in cases of injury to the brain. In fact, men have survived the power or desire of performing the sexual act many years without the testicles being materially reduced in size. We have seen, too, that in the lower animals the testicles have been rendered useless by interrupting the vasa deferentia, without any such striking effect being produced on the glands as occurred in these cases of cerebral injury.

Inflammation of the tunica vaginalis, or acute hydrocele. — The inflammatory changes of the tunica vaginalis resemble those of the other serous membranes. M. Roux injected a hydrocele in a middle-aged man: inflammation was developed, but on the fourth day, gangrenous erysipelas attacked the scrotum, and caused the patient's death on the tenth day after the operation. On examining the tunica vaginalis, he found that it contained a large quantity of whitish serum, in the midst of which floated flakes of albumen; other flakes of the same kind formed a thick coating over the testicle and internal surface of the membranous pouch. The serous membrane beneath appeared slightly thickened, and of a deep red colour. The epididymis and the lower part of the cord were swollen, and constituted the more solid part of the tumour produced by the inflammation. The body of the testicle was not increased in bulk, and it retained its natural consistence.* In the museum of the College of Surgeons, there is a beautifully injected preparation of hydrocele, showing the effects of inflammation after the application of the caustic. It is represented in the annexed wood-cut, which exhibits the sac with part of it cut away to show the swollen state of the epididymis, and the aperture made by the caustic (1); the tunica vaginalis is coated with flocculi of lymph. The sac of an inguinal hernia is seen above the hydrocele. The sound state of the body of the testicle, though surrounded by an inflamed serous tunic, whilst the epididymis partakes in the disease, has been accounted for by Gendrin. He says, when the subserous cellular tissue, which always participates in the inflammation of a serous membrane penetrates into the interior of an organ, it becomes a ready means of communicating

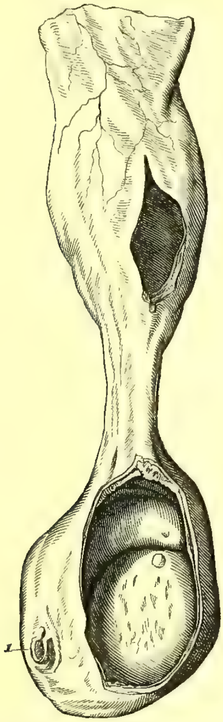
the inflammatory action ; but when the contiguous organ or subjacent part is of a dif-

Fig. 638.



ferent structure from that of the cellular tissue, the extension of inflammation inwards is checked. Thus, in the case of the inflamed tunica vaginalis, the cellular tissue readily transmitted the morbid action to the epididymis, but the tunica albuginea arrested its progress to the body of the testicle ; and this explains the fact that after inflammation of the tunica vaginalis, excited by injection, the body of the gland is rarely found to suffer. On the other hand, the epididymis is seldom attacked with inflammation without the disease being quickly propagated to the tunica vaginalis.

The lymph effused in inflammation very often forms adhesions between the opposed serous surfaces, and these after some time are rendered very firm and dense, and in old cases are often converted into a fibro-cartilaginous structure. In a testicle which I examined some little while after an attack of acute inflammation, I found the lymph on both surfaces of the tunica vaginalis presenting a honeycomb or lace-like appearance, similar to that often met with on the pericardium. Inflammation, if violent, may end in the formation of pus ; suppuration is, however, a rare occurrence, unless artificially excited, for the cure of hydrocele. Inflammation of the tunica vaginalis is not only the most frequent disease of the testicle, but it is also one of the most common affections to which the body is liable. In the different disorders of the gland this membrane usually becomes inflamed at some period or other, and adhesions between its opposed surfaces are scarcely less common than those of the pleura. In examining the testicles of twenty-four adults, I found adhesions of greater or less extent in one or both glands in as many as nine instances.

Hydrocele of the tunica vaginalis.—The sac of the tunica vaginalis, like other serous cavities, is liable to dropsical effusion. The fluid effused is usually transparent, and of an amber, pale yellow, citron, or straw colour, and resembles the serum of the blood, but is occasionally thick. According to Dr. Marcet's analysis*, 1000 grains of this fluid of the specific gravity 1024·3 contained 80 grains of solid matter, of which 71·5 consisted of animal, and 8·5 of saline ingredients : hence it appears that this fluid only differs from the serum of the blood in possessing rather less animal matter. In an analysis of the fluid of hydrocele made by Dr. Bostock†, 100·00 parts of the specific gravity 1024 were found to contain

Water - - -	91·25
Albumen - - -	6·85
Uncoagulable matter -	1·1
Salts - - -	·8
	100·00

A quantity of flakey matter or flocculent albumen is sometimes found floating in the fluid ; and it frequently contains, especially in old people, cholesterine in the form of a multitude of minute shining particles. The quantity of cholesterine contained in nineteen ounces of dark fluid full of these shining particles, which I removed from an old hydrocele, amounted to nine grains. In the examination of a testicle from a man of colour who died at an advanced age, I found the tunica vaginalis and its investing tissues very thick and firm, and the seat of cartilaginous and osseous deposits ; it contained about three drachms of a thick brownish substance, which was almost entirely composed of cholesterine. This was no doubt a very old case of hydrocele, in which, the more fluid parts having been absorbed, the cholesterine was left behind within the indurated sac. The quantity of serum which is suffered to accumulate varies considerably. In this country it seldom exceeds twenty ounces, though it has been known to amount to several pints. The largest quantity which I have met with is forty-eight ounces. Mr. Cline is said to have removed from Gibbon the historian as much as six quarts.‡

In simple hydrocele the testicle is usually found at the posterior part, and rather below the centre, of the sac : its situation however is subject to variations. Before the occur-

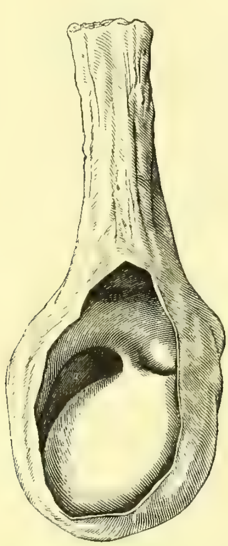
‡ Sir A. Cooper's Lectures, by Tyrrell, vol. ii. p. 92.

rence of hydrocele the tunica vaginalis may have been inflamed and contracted adhesions, so that the testicle may be connected to the membrane in front; in which case the serum accumulates on each side of or above and below the organ. The position of the testicle in front may also be owing to an original inversion of the organ, in which the free surface presenting backwards, the fluid collects in that direction and presses the testicle to the front of the sac. Sometimes there are several adhesions producing a sacculated arrangement and forming what is termed a *multilocular hydrocele*. Occasionally the cysts thus formed have no communication with each other. In two instances I have seen a membranous partition in the sac of a hydrocele, separating it into two distinct cavities, formed by a layer of false membrane. There is one kind of sac or pouch often met with in hydroceles which is not commonly described. It is situated on the inner side of the testicle, but the opening into it is always found on the outer side between the body of the gland and the middle of the epididymis. This sac, which varies very much in size, is formed by the distention of the cul-de-sac which I have described as existing naturally at this part. Two examples of this kind of pouch are contained in the Hunterian Museum. One of them is represented in the accompanying figure. In large hydroceles

Fig. 639.



1, aperture of the pouch between the body of the testicle and middle of the epididymis.

the epididymis is usually elongated and displaced; and instead of a pouch being formed, the central part of the epididymis is drawn to some distance from the body of the testicle. In old hydroceles the sac is often a good deal thickened, the tissues enveloping it being condensed and converted into layers of dense fascia, such as are commonly observed investing only hernial sacs. The fibres, also, of the cremaster muscle, frequently become remarkably developed. This, however, is not constantly the case; for in some instances of hydrocele of large size I have found this muscle atrophied. The thickened sac after many years acquires a cartilaginous character, and it sometimes even becomes ossified. In cases which have been frequently tapped, the sac is often found closely adherent to the skin of the scrotum at the various points perforated by the trocar. In the Hunterian Museum there is a preparation showing a long narrow band of adhesion passing from the anterior part of the testicle across the dilated sac of the tunica vaginalis to the membrane in front, which is supposed to have resulted from a wound of the testicle in the operation of tapping. In all large hydroceles the spermatic vessels are separated and displaced. The glandular structure of the testicle is sound, and the organ capable of exercising its functions. The disease is strictly confined to the investing serous tunic. The testicle is, however, frequently somewhat altered in shape, being flattened by the pressure of the confined fluid; and in some instances has been found partially atrophied.

Hydrocele is generally single, but sometimes occurs on both sides. It is commonly said to form more frequently on the left side than on the right. During the last few years I have registered the new cases of hydrocele coming under my notice in public and private practice. Of one hundred and ten cases of simple hydrocele, one hundred and four were single, and six double. Of the former sixty-two occurred on the right side, and forty-two on the left. This result, which gives a decided predominance to the right side, does not agree with the observations of Velpeau, Gerdy, and Dujat, who found the disease to be more frequent on the left side. Hydrocele in young infants is usually single, and in my experience, more common on the right side. I have seen, however, a few cases of double hydrocele at this early period. When the fluid collected in the tunica vaginalis is attended with enlargement of the testicle, the swelling is termed a *hydro-sarcocele*. This affection is generally consequent on chronic orchitis, but it is occasioned by other morbid changes, malignant as well as innocent. In these cases the disease of the testicle is the original complaint and source of the irritation that excites an undue secretion from the tunica vaginalis.

Congenital hydrocele. — In simple hydrocele, the original communication between the cavities of the peritoneum and of the tunica vaginalis is permanently obliterated; but it sometimes happens that fluid accumulates around the testicle in cases in which the obliteration has not been completed, constituting the variety termed *congenital hydrocele*. The opening of communication between the two cavities is usually small in size, about sufficient to admit a crow's or goose's quill. There is rather a rare variety of congenital hydrocele, in which the testicle is retained in the abdomen or inguinal canal, while the peritoneum, prolonged for a short distance into the scrotum, forms the cyst containing the fluid which is covered only by the integuments and superficial fascia.

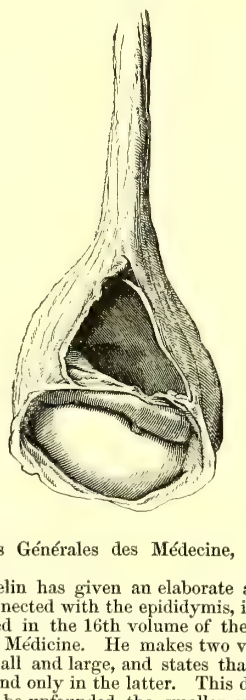
Encysted hydrocele of the testicle. — In this form of hydrocele, fluid is effused into an adventitious cyst or cysts distinct from the sac of the tunica vaginalis. The cyst is composed of a thin delicate serous membrane, and may be developed in three situations: 1. beneath the visceral portion of the tunica vaginalis investing the epididymis; 2. between the testicular portion of the tunica vaginalis and the tunica albuginea, which are thus separated from each other; 3. between the layers of the loose or reflected portion of the tunica vaginalis. The first is by far the most common situation, the two latter being very rare. These cysts are composed of a delicate serous membrane lined with tesselated epithelium, and the fluid contained in them differs from that of simple hydrocele in being perfectly limpid and colourless, and nearly free from albumen. In the cysts formed on the epididymis, the fluid, instead of being limpid, often presents an opaline opacity arising from the presence of spermatozoa.

1. Small cysts not larger than a pea, and even smaller, may frequently be found beneath the serous membrane covering the head of the epididymis, in which they produce a slight depression. In several instances I have seen as many as five and six perfectly distinct cysts connected with this part.

Sometimes one or two small cysts are so embedded in the substance of the epididymis, that they cannot be recognised without dissection. Though these minute cysts generally contain a limpid fluid, I have sometimes found them filled with fluid of a milky hue, and I have even observed matter like pus tinged with blood. These accidental cysts sometimes project the tunica vaginalis before them until they become so far separated from the epididymis, where they were originally developed, as to be attached only by a narrow peduncle formed by a contraction of the connecting tunica vaginalis. Such is the mode of development of those small pendulous pedunculated cysts containing a limpid fluid often found hanging from the head of the epididymis, which were erroneously supposed by Morgagni to be hydatids. I have on many occasions observed them in the different stages of their production. Thus I have seen a pedunculated cyst attached at one part, whilst close to it there was a cyst of a similar nature embedded in the substance of the epididymis. In other instances I have found the cyst very prominent, but still connected by a broad attachment to the tunica vaginalis reflected over it, the membrane not having as yet contracted to form the narrow neck. In all these cases the prolongation of the tunica vaginalis investing the cyst could always be demonstrated by cautious dissection, and between the membrane and the cyst some minute red bloodvessels were generally seen ramifying. These pednuculated cysts never acquire a large size: I have seldom found them to exceed that of a currant. From the exposed situation of the testicle they are liable to be ruptured, the vestiges of them consisting of fimbriated folds of membrane; but this is not a common occurrence. I have seen the delicate peduncle by which the cyst was attached to the epididymis as long as three quarters of an inch. M. Gosselin states that small cysts are sometimes developed in the little appendage to the tunica vaginalis so often found connected with the upper part of the testicle.* This I have never seen.

So common are small cysts connected with the epididymis in the various states and stages I have described, that it is impossible to examine many testicles, especially of persons beyond the age of puberty, without finding them. According to M. Gosselin †, they are liable to be developed from the period of puberty to the age of thirty or thirty-five, but are rare at this period. After the age of forty they are very common, having been met with by him in at least two thirds of the testicles examined. Now when one or more of these cysts, instead of becoming pedunculated, enlarge so as to form a tumour in the scrotum

Fig. 640.



* Archives Générales des Médecine, 4e Série, t. xvi. p. 27.

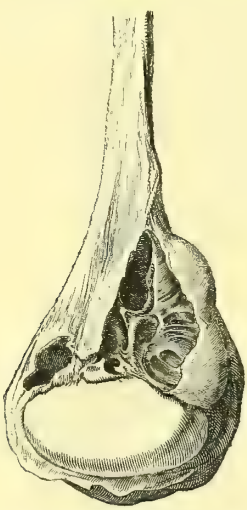
† M. Gosselin has given an elaborate account of the cysts connected with the epididymis, in two papers published in the 16th volume of the Archives Générales de Médicine. He makes two varieties of them, the small and large, and states that spermatozoa are found only in the latter. This distinction I consider to be unfounded, the smaller cysts being simply the early stage of the larger. M. Gosselin assumes the credit of being the first to describe the small cysts. They were, however, minutely described by me, and illustrated in my work on the Diseases of the Testis, published in 1843, of which M. Gosselin could scarcely have been ignorant, since he refers to my account of this form of hydrocele.

they constitute the form of hydrocele, called from its original seat, *encysted hydrocele of the epididymis*. I have observed this description of hydrocele in all its various modifications, from the enlargement simply of a single cyst to the complication occasioned by the varied development of several. As a cyst enlarges the epididymis becomes flattened, and displaced to one side, whilst the testicle is found either in front or at the bottom. It is sometimes at the side, but rarely at the posterior part of the swelling.

In the above woodcut (*fig.* 640.) of a specimen in the London Hospital Museum, the cyst is above the testicle, which is so displaced by it that its anterior edge is directed downwards. The tumour is generally of smaller size than a simple hydrocele, the fluid commonly not exceeding three or four ounces in quantity. I have, however, removed as much as thirty-two ounces from a single cyst. When the hydrocele is composed of several cysts, they are seldom of large size, but form a cluster more or less complicated and irregular, according to their size and number.

A curious sacculated arrangement produced by the development of numerous contiguous cysts may be seen in the annexed figure, (*fig.* 641.) taken from a preparation dissected by

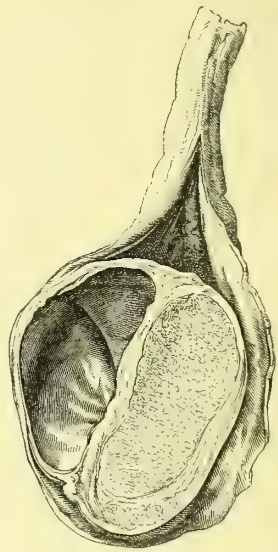
Fig. 641.



myself: part of the walls of the cysts are cut away to exhibit their interiors. The cysts are liable to inflammation, which causes more or less alteration in the quality and appearance of the fluid contained in them. The fluid may become albuminous and assume the straw or amber colour of ordinary hydrocele; and the cyst may contain lymph, form adhesions, or be lined with a false membrane, the fluid being thick and turbid. The cysts sometimes also become filled with blood, constituting a variety of hæmatocele.

2. A cyst may form between the tunica albuginea and the visceral layer of the tunica vaginalis, separating the two membranes which are naturally closely adherent to each other. This is a very rare form of hydrocele. A specimen which I discovered accidentally in dissection, is represented in the annexed woodcut. (*fig.* 642.) The cyst contained about two

Fig. 642.



drachms of fluid, and is situated along the front of the testicle; it is a little thickened. A section of it is preserved in the Hunterian Museum. Sir B. Brodie has described a very similar specimen.* In the museum of St. Thomas's Hospital there is a specimen of a small cyst apparently developed from the epididymis: in its subsequent growth it had extended on the fore-part of the testicle, separating the tunica vaginalis from the tunica albuginea.

3. In examining a healthy testicle I once found six or seven small cysts about the size of currants, studding the surface of the loose portion of the tunica vaginalis. Two of them were situated in a part of the membrane extending up the cord. They projected internally, and contained a limpid fluid. I have twice since seen a similar kind of cyst in the same portion of the tunica vaginalis. Similar adventitious cysts have also been observed on the internal surface of the sac of a simple hydrocele, and a preparation of the kind is contained in the Hunterian Museum. If a cyst developed in this membrane were to increase to any size, it would constitute a swelling which might be appropriately termed *an encysted hydrocole of the tunica vaginalis*.

A circumstance of much interest in connection with encysted hydrocele of the testicle, is the occurrence of spermotozoa in the fluid contents of the cyst, a discovery made by the late Mr. Liston in 1843. During the last six years I have met with them in as many as twenty cases of encysted hydrocele: indeed, in the majority of instances in which

* Lond. Med. and Phys. Journal, vol. lvi. p. 522.

I have searched for them. They were found in subjects of various ages from 30 to 75, and in cysts of all sizes from that of a filbert to the largest which the hydrocele attains. The fluid in some instances contained these bodies in remarkable abundance; in others they existed sparingly. When very numerous, they give to the fluid an opaline opacity, or an appearance resembling cocoa-nut milk which is so characteristic as to enable the surgeon to predicate their presence from the appearance of the fluid alone without minute examination. If the fluid be allowed to remain at rest in a glass vessel, the spermatozoa subside to the bottom, rendering the lower portion more opaque than the upper. The fluid also exhibits slight traces of albumen, when tested in the usual way, which is not the case with the ordinary pellucid colourless fluid of encysted hydrocele. The spermatozoa were often as lively as in fresh semen. They were observed more frequently in the larger cysts than in the smaller. I once found them in fluids removed from two distinct cysts connected with the epididymis of a man about sixty years of age. I have detected them in the fluid from encysted hydroceles tapped for the first time, and also in the examination of small cysts connected with testicles removed after death. I removed from an old man aged 75, who had had encysted hydrocele for eight years, and which had never been tapped before, as much as thirty-two ounces of fluid, which contained an abundance of spermatozoa. They were also detected in fluid taken from a man aged 54, who stated that the tumour had existed for eight years, and had never been operated on.

Various opinions have been broached to account for the existence of spermatozoa in the encysted form of hydrocele of the testicle. The explanation which seems to me the most reasonable and probable, is that which I offered shortly after the occurrence of spermatozoa in encysted hydroceles was first discovered*, viz. that their presence is probably owing to the accidental rupture of a seminal canal, and the escape of its contents into the cyst of an existing hydrocele. The close proximity of the efferent tubes, the slight texture of the ducts and delicate walls of the cyst, and the liability of the part to contusion and injury, when a swelling even of moderate size exists, seemed to me to favour this view. The circumstance that spermatozoa are never found in very small cysts show that they are not originally formed there, but are a subsequent addition to their contents. Since my attention has been drawn to this subject I have investigated the history of the cases of encysted hydrocele containing spermatozoa, which came under my notice. In nearly all instances the patients assured me that the swelling had gradually formed after an injury to the testicle; and in two cases it was clear that a small cystic swelling had long existed in a stationary state, but after a slight blow had begun to enlarge. I strongly suspect that, in these cases, a duct had been ruptured by the contusion, and that the irritation consequent on the injury, and perhaps on the addition of such lively bodies as spermatozoa to the fluid contents of the cyst, had led to its further development. I have, it is true, failed in establishing the fact of a communication between the duct and the cyst by anatomical examination. In two instances of large encysted hydrocele containing spermatozoa, which I had an opportunity of examining, I injected the vas deferens with coloured size, but the duct was so clogged with semen that the fluid could not be made to reach the head of the epididymis, to which the cyst was attached. In a preparation of large encysted bilocular hydrocele containing spermatozoa, shown me by Mr. Busk, the vas deferens had been injected with mercury, but none of the metal reached the upper part of the epididymis. The cyst evidently arose from the head of the epididymis, and was embedded a little in its substance. In these cases no opening communicating with a duct could be discovered on examination of the cysts, but this is not surprising, since the communication must be extremely minute, so as readily to escape detection, or it may even have been obliterated.

Spermatozoa are stated to have been found in some two or three instances in fluid removed from the tunica vaginalis. It is not improbable that these cases may have been encysted hydrocles mistaken for simple. The diagnosis is sometimes very difficult, and in the case of the cyst examined by Mr. Paget,* this error was made before death by a hospital surgeon. I have, however, found spermatozoa in the sac of the tunica vaginalis, and the following case will account for their presence. A man aged fifty-four died in the London Hospital of disease of the kidneys, of one of the ureters, and of the bladder, which appeared to be consequent on a severe blow on the loins about six weeks before. The tunica vaginalis of one of the testicles contained two ounces and a half of slightly opaque fluid, in which a few spermatozoa were found. There were three small cysts containing fluid immediately connected with the epididymis, and also at one spot an irregular ragged membranous appearance, evidently caused by the rupture of a cyst. It is most probable that the spermatozoa had escaped from this cyst, which may indeed have been burst at the time of the injury. I have examined the fluid from the tunica vaginalis in a large number of instances without finding these bodies, and I believe their occurrence in the common form of hydrocele to be extremely rare.

Diffused Hydrocele of the Spermatic Cord.— Mr. Pott has given an admirable account of this affection, under the denomination of *hydrocele of the cells of the tunica communis.*† It has likewise been particularly described by

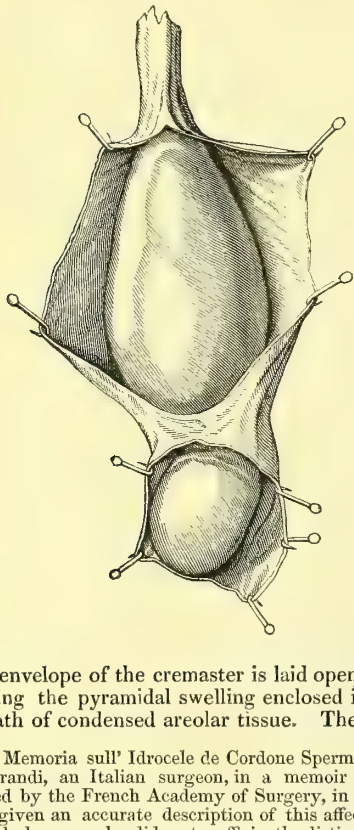
* Practical Treatise on Diseases of the Testis. Appendix, p. 541.

* Medico-chirurgical Trans., vol. 27. p. 398.

† Vide his Treatise on Hydrocele.

Scarpa.* The disease is of the nature of simple œdema, a watery fluid being diffused throughout the areolar tissue connecting the vessels of the spermatic cord, and enclosed in a sheath, which is invested by the musculo-aponeurotic structure of the cremaster muscle. When the complaint has lasted some time, the sheath is found more or less thickened. The areolar tissue within is infiltrated with a limpid albuminous serum of a white or yellowish colour, which flows out in the course of the dissection. The cells infiltrated with serum are converted into large vesicles, some of which are big enough to admit the tip of the finger. These cells are larger and more delicate towards the base of the swelling, where they sometimes disappear altogether; so that there is only one considerable cavity at the lowest and more depending part. The base of the swelling corresponds to the point at which the spermatic vessels join the testicle, and at this part a dense septum cuts off all communication with the tunica vaginalis. In some instances the effusion extends along the cord into the abdomen, as in a remarkable case related by Mr. Pott. In the annexed figure of this affection, (*fig.* 643.), taken from Scarpa,

Fig. 643.



the envelope of the cremaster is laid open, exposing the pyramidal swelling enclosed in its sheath of condensed areolar tissue. The testicle and tunica vaginalis are seen below it. In general anasarca the areolar tissue of the spermatic cord, as well as of the scrotum, is frequently distended with serum; but œdema of the cord alone is a very rare affection. Sir A. Cooper makes no allusion to it, and Mr. Pott, to whom we are indebted for so good and accurate a description of this species of hydrocele, probably met with a greater number of cases of it than have occurred in the practice of any surgeon since his day.

Encysted Hydrocele of the Spermatic Cord.— A cyst containing fluid may be developed in the loose areolar tissue of the spermatic cord. The cyst is formed of a thin transparent membrane, possessing the ordinary characters of a serous membrane, and contains generally a limpid aqueous liquid, having little or no albumen, but sometimes a straw-coloured serum similar to the fluid of simple hydrocele. It is of an oval form, and its size, though variable, seldom exceeds that of a hen's egg, and is usually smaller. It is loosely attached by areolar tissue to the vessels of the cord which are situated at its back part, but become separated and displaced by it. The cyst is invested by the common integuments, superficial fascia, musculo-aponeurotic sheath of the cremaster muscle, and fascia transversalis. It may occur either immediately above the testicle, in the middle of the cord, or just below the abdominal ring, and even within the inguinal canal. Usually there is a single cyst, but occasionally several are developed, and a chain of them has been formed along the cord. The cyst and its contents are liable to changes consequent upon inflammation. Encysted hydrocele of the cord appears to originate, in general, in a partial or imperfect obliteration of the prolongation of peritoneum drawn down at the period of the transition of the testicle. I have already described the different appearances presented by the remains of this prolongation, which, it has been remarked, sometimes consists of a single cyst, or of two or more sacculi, moistened by a serous fluid. When this fluid accumulates in any quantity, an encysted hydrocele is the result. Such is obviously the mode of origin of this affection when occurring in infants, and no doubt in adults it generally originates in the same way. M. J. Cloquet has remarked that the remains of the peritoneal process accompanying the testicles in their descent were met with in male subjects of all ages, and he mentions as a singular circumstance, that they were nearly as frequently found in the old as in the young subjects.* My own dissections agree with the observations of this accurate anatomist. In the museum at the London Hospital there is a preparation showing the tunica vaginalis continued for about two inches up the cord, and, immediately above it, an encysted hydrocele, which was taken from an adult subject. In dissecting the body of a man, aged eighteen, I found an encysted hydrocele of the cord

* Memoria sull' Idrocele de Cordone Spermatico. Bertrandi, an Italian surgeon, in a memoir published by the French Academy of Surgery, in 1778, has given an accurate description of this affection, which, however, he did not sufficiently distinguish from the encysted hydrocele of the cord. He dissected on the dead body a diffused hydrocele, which contained twenty ounces of fluid.

* Description of the parts concerned in Inguinal and Femoral Hernia, tr. by McWhinnie, p. 25.

above the testicle in close contact with the tunica vaginalis. Immediately above this cyst, but quite distinct from it, there was a narrow and empty serous sac three inches in length, with a contracted neck, and communicating with the abdomen. They are figured in the accompanying engraving, with the hernial sac

Fig. 644.

laid open, and part of the parietes of the encysted hydrocele cut away to expose their interiors. The position of the testicle is so changed that its anterior border is directed downwards. In the examination of the body of a man who died of disease of the heart, I found on the right side a thickened and empty serous pouch, extending for about an inch and a half below the external abdominal ring. Directly below it was an independent cyst, capable of containing a walnut, similar in structure to the hernial sac, but lined by a thin false membrane. The tunica vaginalis, which was healthy in structure, extended up the cord as far as the cyst, from which it was separated by a thick and firm partition. In opening the body of a sailor who died with ascites, I noticed at the internal ring a small, delicate, transparent, pedunculated cyst, not larger than a nut, projecting into the cavity of the abdomen. In the spermatic cord, there was a large serous cyst, which extended into the inguinal canal, and contained a small quantity of transparent fluid. A small orifice at its upper part opened into the pedunculated cyst, which proved to be a process from the cyst in the cord. In fig. 644., I have given a representation of an inguinal hernia, combined with an elongated encysted hydrocele of the cord; and in fig. 647., a representation of an encysted hæmatocele of the cord, in which the tunica vaginalis remained unobliterated as far up as the cyst, whilst a hernial sac is situated immediately above it. These dissections confirm the view taken by Sir A. Cooper, and now commonly adopted, of the mode of origin of encysted hydrocele of the spermatic cord in the adult.

Complications of hydrocele.—The following are the principal: 1. Simple hydrocele, combined with encysted hydrocele of the testicle. 2. Simple hydrocele, combined with encysted hydrocele of the spermatic cord. 3. Simple hydrocele, combined with diffused hydrocele of the spermatic cord. 4. Oscheo-hydrocele, including both simple hydrocele and encysted hydrocele, combined respectively with inguinal hernia.

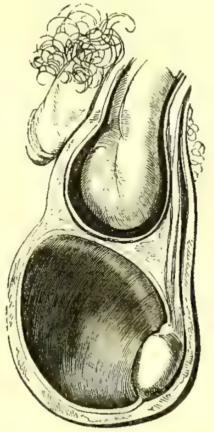
1. The first is not an uncommon complication. In the dissection of these parts, I have often found the tunica vaginalis distended with three or four drachms, and even an ounce or two of serum, two or more small distinct cysts being at the same time connected with the upper part of the epididymis; and I have twice met with this complication in both sides in the same individual. The small adventitious cysts appear to be the original disease, the irritation produced by them being in all probability the cause of the increased quantity of fluid in the tunica vaginalis.

2. The second complication is somewhat rare. In the pathological collection at the London Hospital, there are two specimens of a collection of fluid in the tunica vaginalis associated with an encysted hydrocele of the spermatic cord. In one of them the tunica vaginalis is unobliterated for about two inches along the spermatic cord, and the encysted hydrocele is immediately above it. In the other preparation it is apparent that both sacs have been the seat of inflammation, false membranes being contained within them. This complication sometimes occurs in infants.

3. Simple hydrocele associated with diffused hydrocele of the cord is also rare. A good delineation of this complication is given in Scarpa's work.

4. Scrotal hernia may be combined with hydrocele. A voluminous hydrocele, if un-

Fig. 645.



supported, appears to be highly favourable to the occurrence of hernia and the extension of the sac, by dragging down the peritoneum. Oscheo-hydrocele is not an uncommon complication. In most of the cases which I have met with, the hydrocele was placed below and free of the rupture, and in a few only in front of it. I have never found the hernial sac covering the fore part of a hydrocele. The ordinary relations of hydrocele and scrotal hernia may be seen in the accompanying woodcut. In figure 638., the sac of an inguinal hernia is represented at some little distance above a small hydrocele. Dupuytren states that, when a hydrocele is placed in front of a hernia, a part of the omentum or intestine sometimes descends into a cyst, which projects into the hydrocele, and is formed of the hernial sac and serous fold of the tunic of the testicle.* This complication is of the nature of the *hernia infantilis*, described by Mr. Key, and called by Sir A. Cooper *encysted hernia of the tunica vaginalis*.

Hæmatocele.— This is a term applied to the swelling occasioned by effusion of blood in the sac of the tunica vaginalis, or in a cyst connected with the testicle; it is also applied to tumours produced by extravasation, either in the substance of the spermatic cord, or in the sac of an encysted hydrocele of this part. *Hæmatocele of the testicle*, in which blood is effused into the tunica vaginalis, is by far the most common form of this affection. The extravasation may take place in a healthy state of the parts, or it may succeed, or be combined with hydrocele. The first variety occurs from the accidental rupture of some blood-vessel, probably one of the vessels ramifying between the tunica albuginea and tunica vaginalis testis, owing either to a blow or a violent straining effort. The second variety, in which the extravasation takes place in combination with hydrocele, is of more frequent occurrence than the first. It may also be produced by a blow, or by the wound of some vessel, in the operation of tapping. A blow occasions a slight rupture of the tunica vaginalis, and of some of the enlarged vessels ramifying outside it, and the blood which escapes passes into the sac and mixes with the fluid of the hydrocele, producing a sudden increase in the size of the tumour. The liability to this accidental effusion of blood is increased by a diseased condition of the arteries, such as is commonly met with in old people. The quantity of blood effused under these circumstances varies considerably. It may be merely sufficient to impart a red tinge to the serum. In general, however, it is greater in amount, and coagula are formed, which remain undissolved in the fluid. A hæmatocele may be produced in the operation of tapping a hydrocele, in two ways. It may be occasioned by the accidental wound of some vessel ramifying over the tunica vaginals, which, instead of bleeding externally, or into the areolar tissue of the scrotum, pours its blood into the sac of the hydrocele ; or it may be caused by the trocar or lancet penetrating too far, and wounding the testicle or spermatic artery.

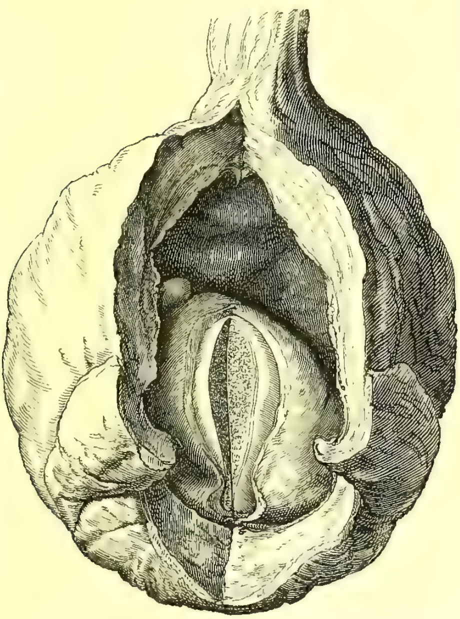
In hæmatoceles which have existed for a long period, the blood becomes changed into a substance resembling coffee grounds, of a brownish-red, or chocolate colour, and more or less fluid. The coagula sometimes present a cellular or honeycomb appearance, the cells being filled with a reddish serum. Occasionally the blood is found converted into a solid fibrinous substance, of a yellow or fawn colour, arranged in firm layers, similar to the coagula lining the sac of an aneurism. In many instances the effused blood is felt as a foreign body, and produces inflammation in the tunica vaginalis, which becomes coated with lymph, and this mixing with blood and serum modifies the appearance of the contents of the cyst, rendering it turbid and of a lighter colour. Sometimes the inflammation goes on to suppuration, in which case pus is also found in the sac. The inflammation usually extends from the tunica vaginalis to the areolar tissue and fascia external to the sac, which in recent cases are found infiltrated with serum and lymph, and in cases of old standing become greatly thickened, indurated, and compacted. In a case of hæmatocele, occasioned by the wound of a vessel in tapping a hydrocele in which I was consulted, the inflammation which ensued caused, in the course of a fortnight, great thickening of the tissues external to the sac, and the formation of an abscess in the scrotum on one side of the hæmatocele. I have found the tunica vaginalis and tissues investing it as much as half an inch in thickness, and very firm and dense.

These changes in the sac are produced by a more chronic form of inflammation of the fascia and areolar tissue investing the sac. In these old cases, the internal surface of the tunica vaginalis instead of presenting its natural smooth and polished surface, is rough, granular, and irregular, and feels as dense and tough as a piece of leather, having lost all the characters of a serous membrane. In hæmatocele, the testicle preserves the same relation to the remainder of the tumour as in simple hydrocele, being situated at the posterior part, and rather below the centre. Its position, however, is liable to similar alterations as occur in hydrocele, and they are dependent upon the same causes. A young man had a hydrocele, which had succeeded to an attack of secondary orchitis, occasioning an adhesion of the gland to the front of the sac at its lower part. The case became converted into a hæmatocele by the wound of a vessel in the operation of tapping. Inflammation ensued, and it became necessary to lay open the sac. The surgeon, in carrying the incision to the lower part of the tunica vaginalis, divided the vas deferens and severed the sound testicle nearly in two with his bistoury, the thickening around the sac having prevented him from detecting the gland in its unusual situation. In hæmatocele, the

* Leçons Orales. Brussels edit. t. iv. p. 233.

glandular structure of the testicle sometimes disappears in the same manner as in old cases of hydrocele, atrophy being occasioned by the long continued pressure arising from the extravasated blood. Sir B. Brodie has recorded two cases of old hæmatocele, in which the testicle was completely atrophied.* In the examination of a large hæmatocele which had existed for many years, and was removed by operation, under the impression that it was a solid enlargement of the testicle, I found the tunica vaginalis nearly half an inch thick, and full of a soft friable substance of a chocolate colour; the testicle, which was situated at the posterior part of the cavity, was somewhat flattened, and partly imbedded in the thickened cyst; but the glandular structure was perfectly healthy, and the bulk of the organ scarcely less than natural. The hæmatocele, with the sac and testicle laid open, is represented in the accompanying figure. The

Fig. 646.



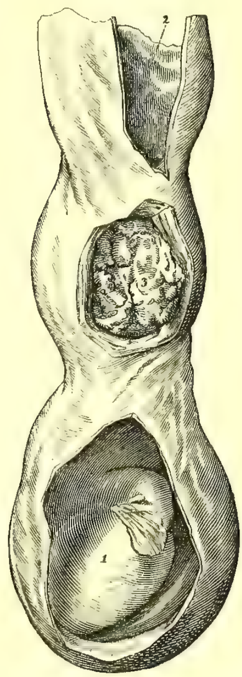
structure of the testicle is usually indeed sound in hæmatocele, but its nutrition becomes impaired when the disease is of very old standing.

Encysted hæmatocele of the testicle, or effusion of blood in a cyst connected with the testicle, is an extremely rare affection. The following is the only case of the kind that I have met with. I was requested by one of my colleagues at the London Hospital to examine a case of painful tumour connected with the left testicle. The patient, aged eighteen, had injured the part three months before. The scrotum was much swollen at the time of the accident, and the tumour formed afterwards. It was about the size of a chesnut, quite moveable, but attached to the epididymis. The cyst was opened with a lancet, and exit given to a quantity of dark coagula lodged in a thickened cyst, the interior of which was lined by a rough false membrane. No doubt the cyst existed before the injury, which caused effusion of blood and inflammation, and thickening of the cyst.

Hæmatocele of the spermatic cord is an affection which was first noticed by Mr. Pott. It is generally produced by the accidental rupture of a spermatic vein, during violent and sudden exertion, as in straining to lift a heavy weight, when blood immediately escapes into, and infiltrates the loose areolar tissue along the cord, where it accumulates, its further diffusion being prevented by the fascious envelope of this part. Mr. Pott has related three cases, all of which happened in this way. I have met with this variety of hæmatocele, coupled with extravasation in the scrotum, in two or three instances of contusion, of this part. In one case in which the effusion in the cord was on the left side the spermatic veins were varicose.

Encysted hæmatocele of the spermatic cord results from the effusion of blood into the cyst of a hydrocele of this part. But it is an affection only known to me from preparations. In the Museum of St. Bartholomew's Hospital there is a specimen of the kind. The cyst is empty: but it is described to have contained blood, and its walls are deeply stained with the colour of partially decomposed blood. Its lining membrane is wrinkled and coarsely granular, and the tissues around

Fig. 647.



1, testicle; 2, hernial sac; 3, encysted hæmatocele.

* Lond. Med. and Phys. Journal, vol. lviii. p. 299.

it are thickened, brawny, and adherent together. In the Hunterian Museum there is a specimen (No. 2460.) of old encysted hæmatocele of the spermatic cord. A good-sized cyst, lined by a membrane, polished and a little wrinkled, is filled with a soft, tawny-looking granular matter, resembling the altered coagulum of blood observed in ordinary hæmatocele after long maceration in spirit. The tissues around the cyst are thickened and indurated, just like those around an old hæmatocele of the testicle. There is a hernial sac immediately above it, and a hydrocele below, with the sac open for some distance up the cord as far as the cyst of the hæmatocele. The latter does not communicate either with the tunica vaginalis, or the hernial sac. In the Musée Dupuytren at Paris, I also saw a preparation of this affection, which occurred in the practice of the late M. Blandin.

Orchitis. — Inflammation of the testicle occurs in two forms, acute and chronic ; and it may commence either in the body or secreting part of the organ, or in the epididymis. Inflammation beginning in the body of the testicle may be idiopathic, or may be excited by external violence: the disease is at first confined to the interior of the organ, the epididymis and tunica vaginalis being affected only secondarily, and sometimes entirely escaping. Orchitis is far more frequently a consecutive affection than a primary, the inflammation being transmitted from the urethra along the vas deferens. In this latter form of orchitis, which is familiarly known by the term *hernia humoralis*, the epididymis is first attacked, and the tunica vaginalis generally participates in the disease.

Acute Orchitis. — Few pathologists have examined a testicle in a state of acute inflammation, and I am unacquainted with any authentic account of the alterations in structure from inflammation originating in the body of the gland. I have twice had the opportunity of examining a testicle affected with acute secondary orchitis ; and the following description of the pathological appearances is drawn up from these investigations, and from the account of the dissection of two testicles affected with gonorrhœal inflammation recorded by M. Gaussail.* The tunica vaginalis is more or less distended with lymph or albuminous matter, infiltrated with reddish serum, which form loose adhesions between the opposed surfaces of the membrane ; these adhesions are so slight as easily to admit of being broken down with the finger. The membrane is injected with a multitude of minute red vessels which ramify in various directions and form a compact network. At a later period red vessels may be traced proceeding from the free surface of the tunica vaginalis to the false membranes forming the adhesions. The volume of the testicle appears very little if at all increased, the great bulk of the tumour being occasioned by the swollen epididymis and effusion into the serous sac. When cut into, the gland appears somewhat darker than natural, from a congested state of its vessels. The epididymis, particularly the lower part, is enlarged to twice and sometimes thrice its natural size, and feels thick, firm, and indurated. This enlargement is produced by the effusion of a brownish deposit in the areolar tissue between the convolutions of the duct. The coats of the vas deferens are thickened, and the vessels ramifying near them injected, sometimes along the whole extent of the duct. Albuminous deposit is found in the areolar tissue around the tortuous part of the vas deferens and tail of the epididymis, which frequently forms the bulk of the swelling observed in these cases. Owing to the epididymis being the part chiefly and most constantly affected in consecutive orchitis, some of the modern French writers have denominated the disease *epididymitis*.

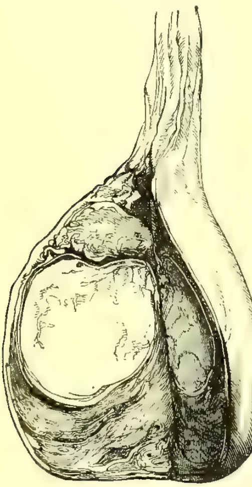
In treating of the acute inflammatory changes in the tunica vaginalis, I particularly remarked that the inflammatory action was very liable to extend to the substance of the epididymis, but not to the body of the testicle, and I noticed the pathological law enunciated by Gendrin, by which the circumstance was accounted for. We find, too, that inflammation of the epididymis is much more readily propagated to the tunica vaginalis than inflammation originating in the glandular structure of the testicle. When inflammation commences in the body of the gland, the enlargement takes place slowly, and is seldom considerable until the disease has existed for some length of time, which is easily explained by the unyielding texture of the tunica albuginea, and the circumstance of the tunica vaginalis remaining unaffected. Suppuration occasionally takes place in this form of orchitis, whereas in consecutive inflammation the formation of pus in the substance of the gland is of rather rare occurrence. I do not mean, however, to assert, that the glandular structure of the testicle never suffers in consecutive orchitis, for I believe that it does so in some instances ; but, according to my observations, and I have paid some attention to the subject, it very commonly escapes, the inflammation not extending further than to the epididymis. When inflammation terminates in suppuration, the matter is so slow in making its way externally, owing to the density, thickness, and low organisation of the tunica albuginea, that it generally burrows in various directions, producing numerous sinuses throughout the gland, and disorganising its delicate structure. The matter sometimes becomes encysted, forming a separate abscess.

In these cases, when the matter effused is small in quantity, after all inflammation has subsided, the more fluid particles are absorbed, and the pus remains for a considerable time in the form of an indolent concrete mass, which has been mistaken, after death, for tubercular deposit. The pus when found in this concrete state appears at first sight very

* Mémoire sur l'Orchite Blennorrhagique, Archives Générales de Médecine, tom. xxvii. p. 210.

like crude tubercular deposit; but on further examination it will be found to be contained in a distinct cyst, from which it may easily be separated, and the structure of the testicle will be perceived to be more or less altered from its healthy state; whereas in tubercular disease, the morbid deposit is in immediate contact with the tubular structure, which, though atrophied by pressure, is usually in other respects sound. Concrete pus may likewise be mistaken for the firm yellow matter effused in chronic inflammation. It differs from it, however, in being friable and easily broken up, and also in being enclosed in a cyst, whereas the yellow fibrinous substance is homogeneous and consistent, and almost inseparably diffused amongst and connected with the convoluted tubuli around it. The distinctive characters just described will be easily recognised on comparing the accompanying representation of concrete pus encysted in the testicle with *fig*. 651.

Fig. 648.

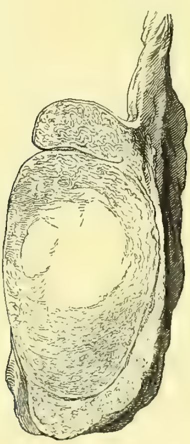


I examined two enlarged testicles taken from a man who died suddenly. Both glands had formerly been attacked with acute inflammation, and for some months before death they had been the seat of chronic pain. In the left testicle, which was the larger of the two, from two to three drachms of thick yellow inspissated pus were contained in a distinct cyst, which occupied the centre of the gland. There was no trace of tubuli, but the remainder of the organ was composed of a fibrous tissue: the sac of the tunica vaginalis was obliterated by close adhesions. The tunica vaginalis of the right testicle contained about half an ounce of yellowish serum and in the centre of the gland there was a small concrete abscess, but the tubular structure was apparent and very little diseased. Pus existing in this concrete or inspissated state often keeps up pain and irritation for a long period, and renders the testicle liable to repeated relapses of inflammation.

Suppuration occasionally takes place in the epididymis. In several cases of consecutive orchitis which have come under my care, at a late period of the disease an abscess formed in the areolar tissue around the termination of the epididymis and inflected portion of the vas deferens, and burst at the most depending part of the scrotum. In many instances, after acute orchitis has subsided, the testicle is restored to its natural condition; in other cases, permanent changes of a serious nature are the consequence. I have observed in testicles that have been affected with inflammation some time before, that the septa appear to be more distinct, and to enter more largely into the composition of the gland than is natural; that the small seminal tubes are less numerous and apparent; and that a great part of the organ is converted into a dense white fibrous tissue, without the presence of tubuli. In these cases the fibrinous matter effused in the areolar tissue connecting the tubuli, not having been absorbed after the cessation of inflammatory action, had occasioned partial atrophy of the proper structure of the organ, and been converted into the dense tissue just described. Complete atrophy is one of the most serious results of acute inflammation of the testicle. I have already remarked that the disturbance in the organisation of the testicle consequent upon inflammation is the most common cause of wasting. Consecutive orchitis, if not checked in the early stage, seldom subsides without leaving behind distinct traces of its existence, which never disappear entirely during the remainder of the patient's life. The epididymis frequently remains enlarged, presenting an indurated irregular knotty swelling, seated usually at its lower part, which is occasioned by the presence of a dense hard deposit between the convolutions of the duct and around the inflected portion of the vas deferens. On making a section of the epididymis in this state, I have often observed not only a highly thickened condition of its duct, but also, in some instances, very considerable dilatation; so that the point of a fine probe might be introduced into the canal without difficulty, its area being increased four or five times. These effusions about the duct rarely if ever produce its obliteration, the yielding nature of the tissues preventing this injurious result. In old cases the epididymis acquires the density and consistence of cartilage, and sometimes even of bone. These changes are rarely found without the presence of old adhesions, obliterating partially or completely the sac of the tunica vaginalis. The coats of the vas deferens are also found for some extent thickened and indurated. The alterations noticed in the body of the testicle have been observed, in some instances, coexisting with those in the epididymis; but in by far the majority of cases, the glandular structure is unimpaired. In only two cases in which the epididymis was thus diseased, have I remarked a decidedly atrophied condition of the organ. The absence of pressure, owing to the unresisting nature of the membrane investing the epididymis, appears to prevent the obliteration of the duct of which it is composed, and thus accounts for atrophy occurring much more rarely after consecutive orchitis than after inflammation originating in the body of the gland, where the delicate seminal tubes are enclosed in the firm unyielding tunica albuginea.

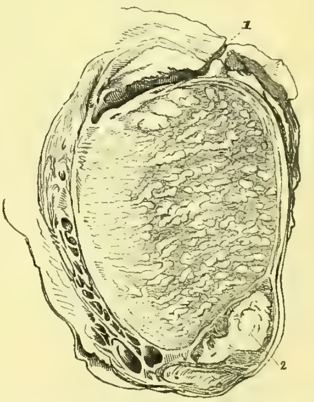
Chronic orchitis. — The testicle is liable to a form of inflammatory swelling of a distinct and chronic character, which occasionally succeeds acute orchitis but far more commonly arises spontaneously. The disease is of importance; for, if unchecked, it tends to disorganise and destroy the gland. The chief anatomical character of this form of inflammation is the deposit of a peculiar yellow, homogeneous, inorganic matter in the structure of the testicle. This substance when first formed is of soft consistence, but afterwards becomes firm and solid, and so closely adherent and intimately blended with the proper structure of the organ as not to admit of separation without much difficulty. In some instances there is a single deposit of this substance in the centre of the glandular structure, as in the preparation from which the annexed woodcut was taken. In others

Fig. 649.



several are interspersed throughout the testicle, portions of sound gland intervening. In a case of chronic enlargement of both testicles taken from a patient who died of *ramollissement* of the medulla spinalis, I found six or seven separate deposits of this yellow matter in the substance of the right testicle, and a single one only in the body of the left. The small masses as they enlarge coalesce, or the single one increases, until the whole testicle presents an uniform yellowish-white appearance. The epididymis is frequently invaded at the same time by a similar kind of morbid deposit, which also tends to obliterate its tubular structure. This, however, is not, as some pathologists suppose, a constant occurrence; for in the majority of testicles thus diseased that I have examined, the epididymis had entirely escaped. I have never succeeded in injecting this deposit, or in tracing vessels into it. But the vessels of the testicle generally are enlarged. Pathologists have differed as to the particular tissue in which this yellow matter is deposited. Sir A. Cooper and Cruveilhier describes it to be seated in the areolar tissue between the tubuli; whilst Sir B. Brodie is of opinion, that it is secreted from their inner surface, as he discovered the yellow substance in the canal of the epididymis and also in the vas deferens which are continuous with the tubuli. I have had the opportunity of inspecting a testicle affected with this disease, in what seems to me to be its early stage from which examination I think I have been able satisfactorily to confirm this opinion. The testicle was injected with red size, and a section then made of it. The surfaces of the tunica vaginalis were partly adherent, and about three drachms of serum were collected in one part of the sac. The body of the testicle was not much enlarged: it contained, however, an abundant deposit of a firm opaque matter. Near the anterior edge of the testicle this deposit appeared in the section like round isolated yellowish-grey bodies, separated from each other by portions of the sound structure of the gland: about the centre of the organ it assumed a beaded arrangement, and towards the mediastinum formed a number of closely-set yellow lines or processes, radiating towards the posterior part of the testicle, where they were amalgamated into one uniform mass. Further examination perfectly satisfied me that this matter was lymph deposited in the tubuli seminiferi. The isolated and beaded appearances in the section resulted from breaks in the lymph thus deposited. The real seat of the effusion was very evident, from the arrangement described near the mediastinum. With a good lens some of the convoluted tubuli could be distinctly seen, filled with and dilated by the morbid deposit. A portion was carefully examined in the microscope with a similar result. The epididymis was

Fig. 650.



1, fistulous sinus leading to the suppurating cavity in the head of the epididymis; 2, concrete abscess in the tail of the epididymis.

much enlarged; its head was filled with soft concrete matter, surrounding an irregular cavity with which a fistulous sinus communicated; its tail contained a similar substance without any external opening. The various appearances described are depicted in the adjoining figure, which was taken from the recent specimen. Similar appearances to those noticed in this case have been described and figured by Cruveilhier, in his "Anatomie Pathologique."* He considers that the disease proceeds from the head of the epididymis towards the tail, and that the body of the testicle is affected only consecutively. I believe, myself, that the yellow deposit is the ordinary result of chronic inflammation of the testicle in whatever way produced; but that the peculiar appearances noticed in the case just related and likewise described by Cruveilhier, — I mean the small isolated masses in the substance of the gland, and radiating towards the mediastinum, — are only observed in those cases in which the disease originates in the epididymis, and thence spreads to the body of the testicle, and in which the part is examined before the organ has become extensively diseased. These appearances are not often seen, because it is not often that it becomes necessary to remove a testicle in such a condition, which is indeed a curable one unless complicated with suppuration. Cruveilhier supposes that this matter is effused in the areolar tissue of the testicle, and radiates along the fibrous prolongations from the corpus Highmori. I feel satisfied, however, from my own observations, that he is mistaken, and that the interior of the tubuli is the original seat of the deposit. This yellow substance has been called the *yellow tubercle of the testis*; but, as it differs from tubercular deposit, the term is objectionable and liable to lead to error. It is evidently coagulable lymph, which becomes more solid in the testicle than in most other parts, owing, perhaps, to the condensation consequent on the firm resistance offered to any enlargement of the gland by the unyielding tunica albuginea. This disease is often accompanied with effusion of serum into the tunica vaginalis, seldom amounting, however, to more than three or four ounces. Lymph also is sometimes deposited, and the sac may become partially, or totally obliterated by adhesions.

The peculiar matter effused in this disease under appropriate treatment undergoes complete absorption, the testicle being left in a condition to perform its natural functions. It sometimes happens, however, that ulceration ensues in its tunics and integuments, and that a fungous-looking growth gradually protrudes through the opening which is thus formed. This fungous growth is sometimes termed *granular swelling*; it has also received the name of *hernia testis*, being formed in a manner very analogous to that of a *hernia cerebri*, in which the substance of the brain is protruded through an ulcerated opening in the dura mater. It appears that the yellow deposit after some time excites ulceration in some part of the tunica albuginea. The tunica vaginalis, and afterwards the skin, become adherent at this spot, and likewise inflame and ulcerate. The resistance afforded by the dense unyielding tunica albuginea being thus removed, the adventitious deposit gradually presses out the tubular structure, which forms a projecting tumour consisting of the tubuli mixed up with this yellow substance, and also of ordinary granulations which spring up from the seminiferous structure. This projecting growth presents an ash or yellowish-white appearance, varied by irregular patches of a pale red hue, and sometimes of black. It is closely girt by the scrotum, the ulcerated edges of which are often thickened and everted. (*fig.* 651.)

Fig. 651.

The mass often projects so much that scarcely any part of the organ is contained within the scrotum. Though this hernial growth occurs most frequently in an advanced stage of the chronic form of inflammation, it is developed in other diseases of the organ which occasion ulceration of the tunica albuginea, and thus afford an opening for the escape of its contents. It is occasionally the result of an attack of acute inflammation supervening upon the chronic disease, and terminating in suppuration in the substance of the gland. In a case of this kind, in addition to the glandular swelling, there are sinuses more or less numerous, which burrow in the interior of the organ, and discharge pus mingled with the yellow matter. An attack of orchitis, originally acute, going on to suppuration, is also liable to be followed by a fungous protrusion of the secreting structure of the gland. In the latter case, the growth is not so exuberant, and the seminiferous structure is more distinctly apparent, owing to the absence of the yellow matter; but there are generally sinuses which furnish a purulent discharge, sometimes mixed with semen. Tubercular matter deposited in the testicle may also lead to suppuration, and the formation of a granular swelling.

A testicle after becoming somewhat enlarged from chronic inflammation, often continues indolent and stationary for years, giving rise to very little inconvenience. On examining the organ in this state, the yellow adventitious deposit is found to possess con-

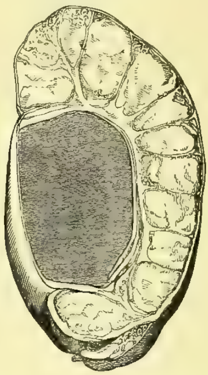
* Liv. v. pl. b., and liv. ix. pl. i.

siderable firmness and consistency; the tunica albuginea is thickened, and in some places as dense and indurated as cartilage; and the surfaces of the tunica vaginalis are closely connected by old adhesions. The glandular structure is partly displaced and atrophied by the pressure of the yellow matter; and it often happens after some time, that both undergo a slow process of wasting, so that an enlarged and indurated gland is progressively reduced, until scarcely any thing remains beyond a mere nodule of the size of a nut at which the spermatic cord terminates. I found, on examination of the body of a man who some few years previously had suffered from chronic inflammation of the testicles, both glands much indurated, but about the natural size. In both, the tubular structure was very deficient, its place being supplied by a dense fibrous tissue. At the upper part of the right testicle there was a yellowish deposit almost as dense as cartilage, and exhibiting very little trace of vascularity. In these indurated testicles the epididymis often escapes the morbid alteration affecting the body of the gland; in other cases, however, the epididymis is also found nodose, irregular, and hard. It will be perceived, from the preceding observations, that the tendency of this chronic disease is gradually to destroy the integrity of the testicle. If the inflammation be checked in an early stage, the gland is left unimpaired; if its course be not arrested until a later period, the secreting structure is partly disorganised and reduced in size; but if the disease be allowed to continue unchecked by treatment, the organ is totally destroyed, either by ulceration of its tunics and the escape of the glandular structure in the shape of a fungous growth, or by the slower process of wasting and absorption.

Syphilitic orchitis is essentially of the same nature as the chronic orchitis just described. It commonly commences in the body of the gland and rarely terminates in suppuration, or in the production of a hernial fungus. Sir A. Cooper states that in the majority of cases the disease attacks both testicles. The eight examples recorded in his work do not, however, bear out this remark; for in only two of them does it appear that both organs were attacked. According to my observation, the disease is more commonly confined to a single gland, though it occasionally affects both: this appears to be the opinion also of Ricord.* The appearances on dissection correspond with those observed in chronic inflammation.

Tubercular Disease. — In the testicle, this deposit is met with in the crude state, forming a yellow caseous substance similar to the tubercular matter occurring in the lymphatic glands. It is sometimes developed in a single mass; at other times several distinct depositions are formed in different parts of the organ: in both cases at the expense of its glandular structure, which becomes atrophied as the disease advances. The epididymis is more frequently affected than the body of the gland. In a specimen taken from a man who died of phthisis, I found the whole of the epididymis occupied by tubercular matter, with scarcely any trace of tubuli; whilst the body of the gland, though small, was perfectly sound and unaffected. (*fig.* 652.) In some

Fig. 652.



cases I have seen two, three, or more distinct tubercular deposits, separated by portions of healthy gland. This was the case in both testicles removed from a middle-aged man who died of phthisis. In some instances these isolated masses appeared to be contained in cysts formed by the processes from the tunica albuginea which separate and support the lobules. Sometimes the separate deposits seemed to be coalescing and joining together, so as to form one continuous mass; and I have found a single mass of tubercular matter surrounded by glandular structure expanded into a thin layer. In other specimens the whole testicle was occupied by a homogeneous cheesy mass, without any trace remaining of the original structure of the gland. In some instances in which the disease was thus advanced, there was very little increase in the size of the testicle; it only felt heavier and harder than in the natural state. In others, again, there was either a general uniform enlargement, or an irregular swelling at some part, commonly at the head of the epididymis. Some of these testicles, in which the disease was not much advanced, when injected made beautiful preparations, the yellow inorganic tubercular matter contrasting in a marked degree with the vermilion hue of the intervening sound portions of the organ. On several occasions I found a small quantity of serum in the tunica vaginalis, with partial adhesions and depositions of lymph. In a further stage of the disease, the characteristic deposit becomes softened down, and converted into a yellow pultaceous substance, evidently tubercular matter mixed with pus. The abscess extends to the scrotum; and after it has burst and the matter has escaped externally, cavities and sinuses are left which may be said to resemble the tubercular cavities in the lungs. The course of the disease, however,

* Traité Pratique des Maladies Vénériennes, p. 640.

in the testicle, more nearly resembles the changes which ensue in tubercle of the absorbent glands.

It has been a question whether the tubercular matter is originally formed in the areolar tissue connecting the tubuli, or in the tubuli themselves. I have certainly seen this deposit in the vas deferens near the testicle, and within the ducts of the epididymis. Dr. Carswell has given a representation of a testicle containing a multitude of pale yellow-coloured granular bodies of various sizes, which, he says, were obviously formed by the accumulation of tuberculous matter in the tubuli seminiferi. The epididymis was as thick as the little finger, and its convoluted ducts were obviously filled with a similar deposit. I believe that tubercle may be deposited in both situations, within as well as between the tubuli. Earthy matter is sometimes found in the testicle, generally in the epididymis, the part most frequently the seat of tubercle. This substance is exactly similar to the putty-looking chalky matter often observed in the lungs and bronchial glands. It is highly probable that, in these cases, the gland had at some former period been the seat of tubercular deposit, but I have not yet been able to establish this point satisfactorily.

Carcinoma. — This disease occurs in the testicle under the four forms of Scirrhus, Encephaloid, Colloid, and Melanosis.

Carcinoma seldom occurs in the testicle in the dense form which it commonly assumes in the breast. Sir A. Cooper describes a *scirrhous* disease of the testicle, in which the gland is invaded by a large white mass in lobes or tubercles. The spermatic cord is affected with a similar disease, and the glands of the abdomen become converted into a white solid texture, very unlike that of the fungoid disease. I have a man, 52 years of age, under my care at the present time, with this disease of the testicle. It forms a tumour about three times the natural size, and is almost of stony hardness, especially at the back part. There is also a large indurated tumour in the spermatic cord. This affection of the testicle is very rare, and is characterised by its slow progress as well as by its great induration.

Encephaloid cancer is by far the most frequent form of malignant disease to which the testicle is liable. When first observed, it is found in one or two masses amongst the tubuli, which gradually become destroyed as the morbid deposit accumulates. The matter is very rarely infiltrated. The testicle at this early period is extremely firm and hard, owing, not to the solid nature of the substance effused, but to the excessive distention of the unyielding tunica albuginea by the morbid growth within. The glandular structure soon entirely disappears, the whole organ being occupied by the new growth, intermixed with and sustained by the septa and fibrous processes from the mediastinum and tunica albuginea. In some instances a thin layer of the tubular structure is found expanded around a mass of encephaloid matter. At this stage the tunica vaginalis is often distended with serum; not, however, in any considerable quantity. The tunica albuginea next gives way, and a portion of the morbid growth protrudes, forming a mass projecting from the body of the gland; this sometimes occurs in more places than one. The epididymis remains for some time unaffected; but, as the disease increases, this part likewise becomes implicated and destroyed. In one instance I found the tubes in the head of the epididymis (the only part of the gland not destroyed) filled with white matter which, on microscopic examination, proved to be carcinomatous. The scrotum in a short time becomes fully distended by the diseased mass, which presents the well-known appearance of encephaloid cancer; viz. a homogeneous substance of the consistence of brain, and easily broken down with the fingers, of an opaque white colour, and variegated with patches of a pinkish hue. It is sometimes mixed with small cysts containing serum; at other times with yellow deposits of lymph, resembling that effused in chronic orchitis. These small depositions of yellow fibrine occasionally interspersed amongst the carcinomatous matter, are almost peculiar to this disease in the testicle. I have only once observed them in cancer of other parts, and that was in the kidney. As the enlargement goes on, the scrotum becomes adherent to the tumour in one or more places, then ulcerates, and allows the protrusion of the morbid mass, which projects as an open fungus. The scrotum admits however of great distention before ulceration ensues. The mass then becomes less firm, and its consistence varies very much in different parts, the morbid matter being in some a mere pulp, or resembling a creamy fluid. It is interspersed with round or irregular patches of dark looking coagula, and, when incised, often presents in different places dark minute spots of various sizes, produced by coagulation of blood in the vascular network usually mixed up with the morbid deposit. On macerating these tumours, or on pouring a stream of water on them for some time, a granular substance, the cancerous matter, is washed away, leaving behind a filamentous shreddy tissue or meshes of a delicate areolar texture, which may often be found connected to a denser fibrous substance, the remains of the tunica albuginea. The spermatic cord is often invaded by a similar substance; and in an advanced stage of the complaint, large bodies of the same kind, originating in disease of the lumbar glands, are found on the sides of the vertebræ, reaching as high up as the diaphragm.

Masses of a similar kind are sometimes also found in the lungs. The carcinomatous matter is often deposited in such abundance as to form a tumour of very considerable size; indeed, there is no other disease of the testicle which occasions solid enlargements of so great a magnitude as encephaloid cancer. M. P. Boyer removed a testicle converted into an encephaloid tumour which weighed more than nine pounds.* The vessels of the cord undergo great enlargement in this disease. In one case which I examined, the spermatic artery was found as large as the radial artery at the wrist. Cancerous germs have also been found in the blood contained in the spermatic veins. Encephaloid cancer of the testicle occurs at all periods of life: no age, indeed, can be said to be exempt from it. There are examples on record of operations for the removal of testicles thus affected, within a twelvemonth after birth. On the other hand I have met with the disease as late in life as the age of sixty-four. It more commonly occurs, however, in the middle period of life, or between the ages of twenty and thirty.

Carcinoma has, in some few instances, been found to originate from the tunica vaginalis, the glandular part of the testicle remaining for some time unaffected. Cases of the kind have been recorded by Sir E. Home† and Sir A. Cooper. The other two forms of cancer, *colloid* and *melanosis*, have rarely been observed in the testicle. A preparation of the former disease is contained in the Museum of Guy's Hospital. The organ is enlarged to four or five times its natural size, but preserves its oval form: there is scarcely any trace of the natural structure remaining, its place being supplied by colloid matter. Cruveilhier has related the case of a man who died of melanosis affecting the hand, lungs, heart, stomach, and other parts. There was a deposit of the same character in each testicle.

Cystic Disease. — The cysts developed in the substance of the testicle and constituting this disease vary very much both in number and size, and in the appearance of their contents. They may be only two or three in number, or they may exist in a countless multitude and occasion considerable enlargement of the organ. They vary in size from that of a millet seed to the dimensions of a pigeon's egg. At an early period they generally consist of smooth and slightly vascular cysts, closely adherent, and containing a transparent light-coloured fluid. In other cases the fluid is thick, viscid, and highly albuminous, and sometimes tinged with blood. I have never succeeded in detecting spermatozoa in the fluid. Sometimes a small lobulated growth arises from the walls of the cyst, and increases until it is partly or wholly filled and obliterated. The cysts usually increase at the expense of the secreting structure of the testicle, which disappears or becomes much displaced. In some instances the tubular structure forms an expanded layer over the morbid mass. When inflammation takes place, fibrine is effused between as well as within the cysts, and becomes organised; so that the tumour is partly solid and partly composed of cysts containing fluid. After some time, the surfaces of the tunica vaginalis become more or less adherent, and in old cases the tumour is intersected with fibrous bands. In several specimens of the disease I have noticed small masses of enchondroma interspersed amongst the cysts. In sections the little pearly-looking masses appear as if contained within the cysts. They are however developed between them, and are closely connected with their walls. The occurrence of enchondroma in these cystic tumours has scarcely been noticed by pathologists. There are several specimens in the Museum of the College of Surgeons.

Fig. 653.

Portion of the section of a testicle in the Museum of the College of Surgeons, with numerous masses of enchondroma between the cysts, of the exact size.
a. a. enchondroma.

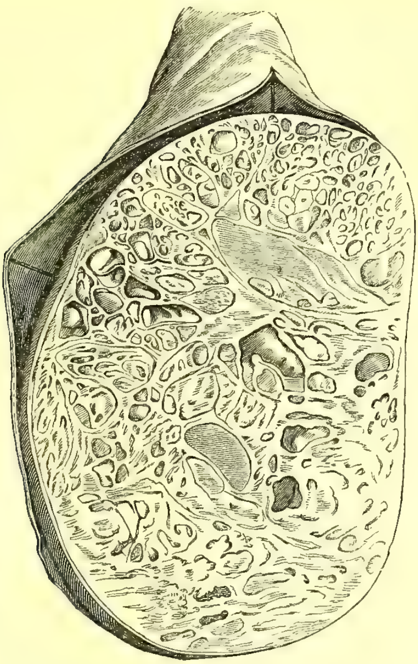
One of the specimens of cystic disease in this collection measures five inches in its largest diameter, and three inches in its smallest. Sometimes small lobulated growths arise from a part of the walls of the cyst, and increase until the cavity is partly or wholly filled and obliterated by them, in the same manner as in cystic disease of the mamma.

The mode of origin of these cysts has not been satisfactorily made out. It has been supposed that they are formed of dilated and obstructed seminiferous tubes; but as in certain cases the tubular structure exists in the form of a layer spread over the morbid mass, it is clear that the disease could not have originated in this way. This morbid change is evidently quite distinct from the little cysts so commonly developed in the head of the epididymis: indeed this part is rarely affected in cystic affections of the testicle. The disease is considered by some pathologists to be of a malignant character. After removal of a testicle thus diseased, tumours of a carcinomatous character have afterwards appeared in the lumbar glands and other parts. Mr. Cæsar Hawkins showed me several preparations of cystic sarcoma of the testicle which had been removed by operation where this happened, and it occurred also in a case which came under my own observation. The unexpected result in this instance led me to pay attention to the matter, and I am now quite satisfied that the cystic disease may be

* Revue Médicale. Nov. 1839.
† Observations on Cancer, p. 125. Anatomie Pathologique, liv. xix. pl. 3, 4.

developed under two forms. In one, it occurs in combination with carcinomatous deposit:

Fig. 654.



Section of a cystic tumour of the testicle, showing a multitude of cysts of various shapes and sizes, with solid matter interposed betwen them. The natural glandular structure is wholly destroyed.

in the other and more common form, the tumour is of an innocent character, and free from the risk of disease attacking other parts after removal of the organ. In the former the cysts are larger and less numerous than in the latter. By careful examination and with the aid of the microscope the coexistence of the two diseases may generally be made out.

Ossific deposits in the testicle. — Earthy matter occurs in the testicle under two forms: 1. Laminated, and often mixed up with cartilage; and 2., as an inorganic deposit. In the first form it is usually deposited between the tunica vaginalis and tunica albuginea, in little bony or cartilaginous patches, in which a fibrous arrangement may be recognised. I have frequently found one or two irregularly-shaped projecting ossific bodies scarcely larger than a pin's head attached to the upper part of the testicle. Ossific matter occurs also on the adherent surface of the tunica vaginalis in old cases of hydrocele, where it has been found so abundant as to form a complete ossific capsule. It has been said that the epididymis alone may be encased in bone, the testicle being free; this I have never seen. Bony matter occurs, however, in the substance of the epididymis as the result of ossification of the product of inflammation. Earthy matter in this form is not often observed in the substance of the testicle. The gland, however, when atrophied and reduced to a mere fibrous tissue, occasionally undergoes both the cartilaginous and osseous transformation. The cysts developed in the testicle, as I have already shown, are liable to similar changes.

In the second form the earthy matter is deposited in an irregular mass, containing very little animal matter; in appearance resembling mortar, and very similar to the earthy substance found in the lungs and bronchial glands. It is generally met with in the head of the epididymis, and sometimes in the lower part, and but very seldom in the body of the testicle. As I have already stated, it is most probable that this earthy matter results from the transformation of tubercular matter deposited in the testicle in early life.

Loose bodies in the tunica vaginalis. — Loose bodies are occasionally found in the cavity of the tunica vaginalis. They are small in size, and of an oval flattened shape, and their surface is smooth and polished. Their texture is in most instances elastic and homogeneous, resembling the unattached cartilages found in joints, and points of ossification are often contained in their interior. In some specimens I have observed the cartilaginous matter to be arranged in concentric laminæ. The loose body is sometimes entirely composed of bony matter. On examining a thin lamina of one in the microscope, I could distinctly see small oval corpuscules with a number of lines proceeding from them very similar to those of bone. They seldom exceed three in number, and they occur generally in combination with hydrocele, the loose bodies being the original disease.

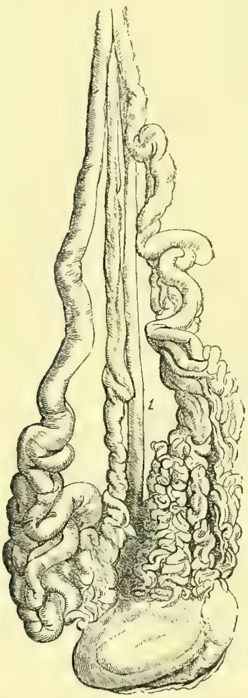
Fœtal remains in the testicle. — The remains of a fœtus have been found in some rare instances, in the scrotum, in connection with the testicle. Several examples of the kind have been collected by Ollivier (D'Angers).* In all these cases it was evident that the scrotal inclusion had succeeded to an inclusion originally abdominal; that is to say, that the organic *debris* were first situated in the abdomen in connection with the testicle, and had accompaniad the gland in its passage out of that cavity. In the cases in which the particular testicle was indicated, the right was the one affected.

Varicocele is a term applied to a morbid dilatation of the spermatic veins. On dissection they are found dilated, elongated, and more tortuous than natural, and apparently more numerous, owing to the enlargement of the smaller vessels. In an advanced stage of the disease, their coats are thickened; so that when divided the vessels remain patent, and thus present the appearance of arteries. The enlarged veins hang down below the testicle, and reach upwards into the inguinal canal; and when very volu-

* Mémoire sur la Monstruosité par Inclusion; Archives Génerale de Médicine, t. xv. p. 540.

minous conceal the gland, encroach on the septum, and extend to the other side of the scrotum. In a specimen which I carefully examined, the vessels were arranged in three clusters (*fig.* 655). One formed of the larger vessels proceeded from the inferior extremity of the testicle; the second, in which the vessels were less in size, but more numerous and tortuous, arose from the upper ex-

Fig. 655.



tremity of the testicle; whilst the third and smallest cluster surrounded and accompanied the vas deferens (1). The dilatation is not confined to the veins exterior to the gland: even those in the organ itself are varicose, and enlarged veins may often be distinctly seen ramifying between the tunica vaginalis and tunica albuginea. The veins occasionally contain phlebolites which are lodged in dilatations of the vessels. The veins of the left testicle are more subject to varicocele than those of the right. In upwards of 120 operations performed by Breschet, in only one instance was the varicocele on the right side.* Pott met with this disease on both sides of the body in only one instance. The disease, however, is far from being so rare on the right side as is generally supposed, and often exists on both at the same time, although the varicose state of the right spermatic veins is always much less than that of the left. Of the causes of varicocele, some operate on both sides, others only on one. The most influential of the former is the hydrostatic pressure consequent upon the depending position of these veins, which have to support the weight of a column of blood extending from the testicle to the second dorsal vertebra. The absence of valves is mentioned as a circumstance conducing to this disease; but this is an error, for the larger spermatic veins are always furnished with valves, though the dilatation which takes place in varicocele prevents them performing their office. There are several anatomical circumstances, which, taken together, are sufficient to explain the frequency of varicocele on the left side. On the right side the spermatic vein joins the vena cava nearly parallel to the axis of that vessel, so that the blood enters in the course of the circulation; but on the left side the spermatic vein terminates in the emulgent vein at a right angle, and in a direction perpendicular to the venous current from the kidney, which is less favourable to the return of blood from the testicle, since the two currents pursue a different direction. The left testicle hangs lower than the right, consequently the veins must be longer, and the pressure produced by the column of blood greater on the left side than on the other. The accumulation of the fæces in the sigmoid flexure of the colon previous to an evacuation tends to produce pressure on the spermatic vein, and impede the return of blood from the left testicle, especially in persons whose bowels are habitually constipated. Some persons subject to varicocele suffer from it only when the bowels are in this condition. But even the natural daily accumulation may be sufficient to produce obstruction. To this cause, we must chiefly attribute the circumstance that a varicose dilatation of the veins of the ovary in the female is nearly always confined to the left side.

In the slight degree and chronic state in which we most frequently meet with this affection, no injurious effect is produced on the testicle; but when highly or rapidly developed, the dilatation of the veins interferes so much with the nutrition of the gland as to occasion wasting. A partial atrophy of the gland, coexisting with varicocele has come under my notice in more than twenty instances; indeed, in nearly all cases in which there was a decided dilatation of the spermatic veins on one side only, the testicle of that side was the smaller of the two. In a man, aged fifty-six, with a varicocele on the left side, the testicle was so reduced that it scarcely exceeded the usual size of the organ in an infant. Some years ago, a tall sailor was under my care on account of a varicose ulcer on the left leg, who had a large varicocele on the left side, and a testicle so wasted, that it could scarcely be felt through the tunica vaginalis, which was loosely distended with fluid. The period of puberty is the time at which varicocele most commonly occurs. I have met with very few cases before that age.

Adipose tumours. — The spermatic cord may be the seat of abnormal depositions of fat. They occur at different parts, as high up

* Landouzy, Du Varicocele, p. 24.

as the inguinal canal, and as low down as the epididymis. In examining the testicles of a young man who died of pleurisy, I found a quantity of fat along the cord, and around the epididymis, and some also beneath the tunica vaginalis covering the posterior part of the testicle. In another case I met with small isolated masses of fat, coupled with a small encysted hydrocele of the cord. When developed in considerable abundance this deposit sometimes forms a tumour either in the groin or in the scrotum. A tumour of this kind in the scrotum has been mistaken for omental hernia. I once dissected a lobulated fatty tumour, surrounded by the thickened sheath of the spermatic cord, on the body of a man upwards of eighty years of age, which was very similar in appearance to a portion of omentum contained in a hernial sac. A mass of fat, however, in the cord may form a more defined and distinct swelling. Such a tumour is preserved in the Museum of the College of Surgeons. (No. 2461.) It is embedded about an inch above the testicle, in the tissues of the spermatic cord and loosely connected with them. Its shape is oval; it measures four inches in length, and consists of numerous lobes of soft fat, closely held together by their thin fibro-cellular partitions. An interesting case of large fatty tumour in the scrotum, originating in the spermatic cord, was seen by several surgeons, in 1844, much difficulty having been experienced in making out the nature of the swelling. The tumour, together with the testicle, was excised by Mr. Lawrence.* Another of the same character, but of smaller size, subsequently formed in the remains of the cord in the groin, and was excised by me in May, 1849. Collections of fat in the scrotum have been known from the time of Galen by the term *steatocele*. I suspect that they all originated from the spermatic cord.

Morbid anatomy of the scrotum. — The morbid appearances presented by the scrotum, when the seat of *œdema*, *inflammation*, and *mortification*, so closely resemble those of other parts where loose areolar tissue abound, that they require no particular description.

Elephantiasis. — This disease of the scrotum is rarely seen in Europe, but is of very common occurrence in many other parts of the globe. It consists in a morbid thickening, or hypertrophy of the tissues of which the scrotum is composed. The epidermis becomes thickened, rough as in icthyosis, and intersected with fissures, or chaps. The corium is excessively consolidated, and often nearly an inch in thickness, and very dense. The chief bulk, however, of the tumour, is formed by the conversion of the loose areolar tissue of the scrotum into a large mass of fibrous tissue, infiltrated with a thick jelly-like fluid, evidently albumen, as it coagulates on the application of heat, acid, or alochol, and sometimes on cooling after its removal from the body. The areolæ of this tissue vary a good deal in size, but some of them have been found large enough to admit the extremity of the little finger. Examined in the microscope this structure exhibits the white and yellow elements of the areolar tissue, in some instances mixed with fat cells. When the part is condensed by inflammation, there are often hardened masses in the substance of the tumour, which has a lardaceous appearance when cut, or resembles cartilage; they sometimes undergo conversion into bone. The testicles are buried in the morbid mass towards its posterior part, but they are usually sound in structure. Occasionally there is a small quantity of serum in the tunica vaginalis. In a case operated on in Calcutta, there was a hydrocele on both sides imbedded in the diseased parts, the largest of which contained between five and six pints of fluid.* The spermatic cords are elongated several inches, owing to the testicles being gradually dragged downwards during the growth of the tumour, but the cords are not otherwise diseased. In the remarkable case of Hoo Loo, a native of China, operated on by Mr. Key, in Guy's Hospital, the cremaster muscles were nearly as thick as the finger. The morbid growth is not very vascular. Its arteries are derived chiefly from the external pudic and perineal vessels; but these, owing to the magnitude of the tumour, become greatly increased in size. The veins are numerous, large, varicose, and very tortuous.

The integuments of the penis are often affected with a similar disease, and enlarge in the same ratio as the scrotum. In cases where the disease is confined to the scrotum, the penis becomes drawn in and ultimately disappears, being completely imbedded in the tumour; whilst the prepuce being elongated, opens by a navel-like aperture on the anterior surface of the tumour, as may be seen in the subjoined woodcut. In confirmed cases of elephantiasis, the tumour increases until in the course of years it attains an enormous magnitude. As this takes place, the skin is borrowed from the lower part of the abdomen, so that the hair on the pubes becomes thinly scattered on the front and upper part of the tumour. The tumour assumes an oval or pyramidal form, the apex being superior, and is attached to the body by a thick peduncle extending from the pubes, occupying the whole of the perineum, and terminating posteriorly at the verge of the anus. There is scarcely any limit to the size which the tumour may attain. It has been known to acquire such a magnitude as to weigh more than two hundred pounds†, exceeding the weight of the rest of the body. It has been found to measure more than four feet in cir-

* Vide accounts of this case by Lawrence, Medical Gazette, May 30. 1845; by Brodie, Lectures on Pathology, p. 271.; by Edwards, and myself, in Provincial Med. and Surg. Journal, June 25. 1845.

† Case cited from Ephémérides d'Allemagne, by Larrey. Mémoires de Chirurgie Militaire, t. ii. p. 115.

cumference, and almost to reach the ground when the patient is in the upright position. In a case operated on by Clot Bey in Egypt, the morbid mass, which weighed one hundred and ten pounds, kept the patient's legs far apart, and obliged him to remain constantly on the ground; it was so bulky that he could even sit upon it. In the accompanying figure

Fig. 656.

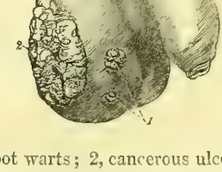
of a black man, affected with elephantiasis, taken from Dr. Titley's work on "Diseases of the Genitals, in the Male," the tumour descended nearly to the ankles.

Elephantiasis of the scrotum is a morbid affection of the integuments, analogous to the enlargement of the extremities commonly known by the name of *Barbadoes leg;* with which, indeed, in those countries where the disease is prevalent, it is liable to be combined. Elephantiasis of the scrotum, however, grows to a greater size and makes more rapid progress than the same disease in the leg, owing to the very loose texture and depending state of the parts. The labia pudendi of females in warm climates are subject to a similar change, though not to the same extent nor so frequently as the scrotum. This disease appears to be the result of a low form of inflammation of the veins, and to be analogous to the affection termed *phlegmasia dolens.* It is preceded by febrile attacks, attended with pain and heat in the part, and swelling and tenderness of the glands in the groin. After a time, the scrotum continues to enlarge, independently of febrile attacks. In December, 1847, I saw a gentleman, from Barbadoes, who had this disease in the early stage. The whole scrotum was considerably enlarged, forming a doughy inelastic swelling, fissured in two or three places. A portion of skin at the root of the penis was a little red and puffy as if affected in a slight degree. The glands in the left groin were enlarged, but those on the right side were unaffected. The testicles were sound.

Hypertrophy of the scrotum is an affection of the same nature as the knotty and lobulated growth of the skin occasionally observed on the nose and in other parts. In this disease the integuments appear as if composed of lobes divided by fissures. In the Museum of St. Bartholomew's Hospital there is a preparation of this kind, but no history is attached to it. The hypertrophied scrotum appears to have been removed during life. Many years ago I saw a case of the kind at the hospital of La Charité in Paris. The patient was a young man whose scrotum was hypertrophied to about four times its natural size. This disease is liable to be confounded with elephantiasis, but differs from it in the circumstance that the morbid enlargement is entirely confined to the skin, the subcutaneous areolar tissue being unaffected.

Cancer Scroti, or, as it is commonly called, *chimney sweeper's cancer*, is a disease of the skin, which attacks the scrotum of persons who have been exposed to the contact of soot. It is originally developed in the form of a small pimple or warty excrescence, termed *soot-wart*, which often remains on the scrotum for months or even years without undergoing any change. Usually, there is only a single wart at the lower part of the scrotum; sometimes there are two or three of different sizes; and occasionally they are so numerous and so abundantly and largely developed as to form a considerable cauliflower excrescence. After a time the wart becomes soft, excoriated and red, and exudes a thin irritating discharge, which becoming dry forms an incrustation over the excrescence. After the scab has been picked off, or rubbed off by friction against the dress, ulceration ensues, destroys the wart and produces a painful chronic sore, possessing the ordinary characters of a carcinomatous ulcer on the skin, — thick, indurated and everted edges, and an irregular excavated base, the surface of which discharges a thin sanious fluid. The ulcer, if suffered to proceed, in-

Fig. 657.

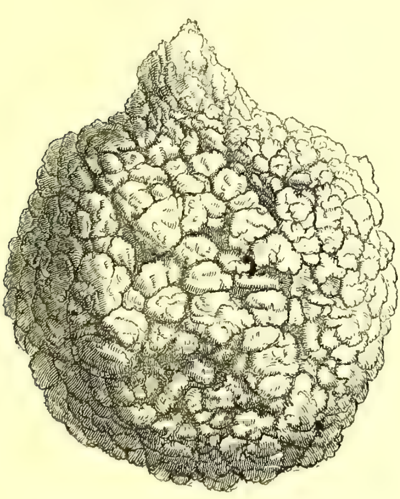


1 small soot warts; 2, cancerous ulcer succeeding the wart.

creases widely, invading the whole scrotum to the perineum, and laying bare the crura penis. At the same time it penetrates deeply to the tunica vaginalis, which becomes firmly connected to the morbid scrotum and adherent to the testicle. This organ may also become involved in the disease, and be the seat of a deep excavated sore. The glands in the groin often enlarge at an early period from irritation; but at length they become indurated and diseased. The inguinal glands sometimes suppurate, and form intractable ulcers in the groin similar in character to the sore on the scrotum. The ulcer spreads towards its circumference widely and superficially, whilst in the centre it burrows deeply until in many instances it reaches the great vessels of the thigh, destroys their coats, and causes death by hæmorrhage. In other cases the glands remain unaffected, but ulceration advances slowly in the direction of the cord, and a frightful sore is produced.

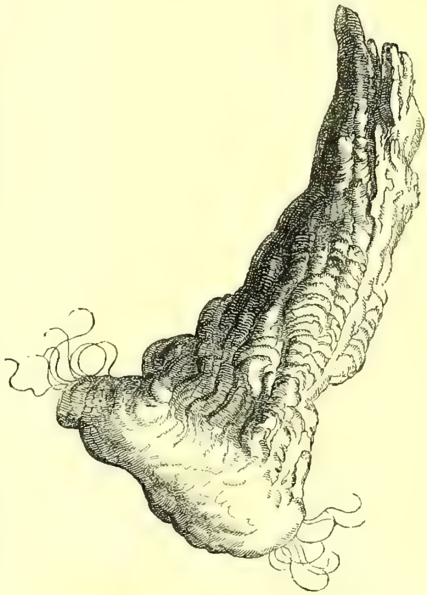
The small excrescence in which cancer scroti usually originates is soft, vascular, and sensitive; and in many respects similar to the soft warts which occur on the internal membrane of the prepuce and on the glans penis. The soot-wart appears, in fact, to consist of a congeries of morbidly enlarged papillæ. The Museum of the London Hospital contains a remarkable specimen of chimney-sweeper's cancer, in which nearly the whole scrotum is occupied by a cauliflower excrescence, which exhibits these papillæ in a very advanced state of developement. It was removed from an old man, about sixty-four years of age, who afterwards left the hospital cured. The morbid growth is composed of a number of projecting processes densely grouped together, of variable size, but many very large, with their summits lobulated, expanded, and elevated on narrow peduncles, more or less flattened. They are represented in the subjoined engraving. The soot-wart is sometimes covered with a dense and thick concretion, formed

Fig. 658.



by successive layers of incrustation, the superficial still remaining attached, so as to form a projecting elongated conical process, which is not unlike the spur of the cock, and when very long is occasionally twisted like the horn of a ram. Some curious excrescences of this kind are represented in the clever etchings of Mr. Wadd.* The subjoined figure taken

Fig. 659.



from one of them, exhibits the process of its exact size.

Upon dissecting a portion of scrotum affected with chimney-sweeper's cancer, the part is found to present very similar appearances to those of carcinoma of the lip. The tissue at the base of the ulcer is dense, indurated, and distinctly laminated, and possesses very little vascularity. On examining some matter scraped from the base of a soot-wart shortly after its removal from the body, I perceived a number of caudate and spindle-shaped nucleated cells. Epithelial cells have likewise been observed in several cases, and the disease is regarded as belonging to the epithelial form of cancer. On examining some diseased glands in the groin in a case of scrotal cancer, I found them enlarged and indurated, and composed of a whitish brown or yellowish white substance, mixed up in some places with a soft curd-like matter, or greyish pus, contained in thin white cysts.

Carcinoma scroti is, with few exceptions, confined to chimney-sweepers; and the irritating action of the soot on the skin of the scrotum is no doubt its exciting cause. A similar disease occasionally occurs in other parts of the skin, but the scrotum being seldom cleansed and well adapted to harbour soot

* Cases of Diseased Prepuce and Scrotum, pl. x. xi. xii.

seems more exposed to the disease. Sir James Earle has related the case of a man who had a large sore resembling chimney-sweeper's cancer which reached from the bend of the wrist to the knuckles, occupying almost the whole of the back of the left hand. The man was a gardener, and for several springs had been in the habit of strewing soot on the ground round the young plants to preserve them from slugs. He carried the soot in an old garden pot which hung on his left hand, while he strewed the soot with his right.

The predisposition to cancer scroti appears in some instances to be hereditary. The late Mr. Earle extirpated the testicle and diseased integuments from a sweep aged thirty-five, a patient in St. Bartholomew's Hospital, whose grandfather, father, and one brother had all perished from the effects of the disease. A father and son were once in St. George's Hospital at the same time on account of it. Mr. Cusack mentions that he removed a soot-wart from the hand of a female who carried on the business of chimney-sweeping, and that he had previously excised an excrescence of the same nature from the ear of her son.*

Cancer scroti occurs more commonly at the middle period than at any other time of life. In the majority of cases which I have met with the disease occurred between the ages of thirty and forty. Those exposed however to the action of soot may become affected at a much earlier period. Mr. Wadd has figured a diseased prepuce and soot-wart on the scrotum from a boy aged fifteen; and Sir J. Earle witnessed a case of the disease as early as at eight years of age. It appears that the seeds of this malady are sown in early life, but in general do not germinate until they have remained for some time dormant in the system. What is the permanent effect on the scrotum produced by soot, which thus renders it in certain individuals so peculiarly susceptible of a cancerous action at some distant period, we cannot explain; but that the soot, though the exciting cause of the disease, may in some instances be a remote one, is shown by several striking facts. It is known that persons who have been sweeps when young, but have abandoned the occupation, have afterwards been attacked with chimney-sweeper's cancer, although they have long been removed from all contact with soot. A sailor between forty and fifty years of age, was admitted into the London Hospital, with an ulcerated sore on the scrotum, presenting all the characters of genuine chimney-sweeper's cancer. The inguinal glands were indurated and enlarged, and subsequently ulcerated. He had been brought up as a sweep; but for the last twenty-two years, during which period he had served at sea, he had not been employed amongst soot in any way whatever. The disease first appeared in the scrotum about three years before. In this case, therefore, the injurious influence of soot must have been exerted nineteen years before the appearance of disease, during which long period he was entirely removed from the effects of its exciting cause. It has sometimes happened, after the morbid parts had been completely extirpated, and the wound healed, the patient having avoided further contact with soot, that the disease has re-appeared as it were afresh, a second and even a third time; not, however, in the cicatrix of the wound, but on a different part of the scrotum. These, and similar facts, lead to the conclusion that though abandonment of his occupation may render the adult chimney-sweeper less liable to cancer, it by no means forms a satisfactory security against its occurrence.

Cancer scroti chiefly extends its ravages by affecting the contiguous tissues, and has little disposition to contaminate the lymphatic glands or distant parts. An instance is on record of an old chimney-sweeper, who had been subject to this disease for forty years, and had undergone three operations for its removal, yet even then the glands in the groin were unaffected.* A man aged fifty-one who had been a chimney-sweeper ever since the age of seven years, was a patient of mine on account of this disease. He had been repeatedly attacked with it during a period of twenty-two years, and had submitted to no less than five operations for its removal. The glands in one groin became affected only a few months previously. Ulceration took place, and the patient died from its irritative effects on the constitution. On a careful examination of the body, no trace of internal disease could be detected. The cancer was strictly limited to the groin and scrotum. Mr. B. Cooper has likewise recorded a case of chimney-sweeper's cancer which ended fatally; and on examination none of the glands or viscera of the interior of the body were affected.† These cases show that, when the inguinal glands are indurated, they may be excised with a fair hope of a successful result.

Melanosis. — Notwithstanding the dark colour of the skin of the scrotum, melanosis is an exceedingly rare affection of this part. Indeed, the only case of its occurrence there with which I am acquainted, is one that happened in my own practice. The patient was a cabinet-maker, aged thirty-two, and the disease commenced as a small dark spot, apparently produced by some black deposit beneath the epidermis, raising it a little above the surrounding surface. This spot increased until it formed a fungous growth. I excised the part, but the disease re-appeared in the scrotum and in the glands of the groin six months afterwards. It made, however, very slow progress, and did not destroy the patient for six years.‡

Fibrous tumours. — A small fibrous tumour is occasionally developed in the areolar tissue of the scrotum. It may acquire the size of the testicle, and being firm and of an oval form, resembles a supernumerary gland. I have met with only one case of this form of tumour. Dr. Mott, of the United States, excised an enormous mass from the scrotum of a man about seventy-three years of age. The scrotum was twelve to fifteen times its ordinary bulk, and was filled with tumours of a stony hardness, from the size of a nutmeg to that of a large pea. The tumours had all a very white appearance, and the integuments over two or three of the largest, having been ulcerated for upwards of a year, poured forth a fœtid discharge, together with a white substance resembling mortar. The disease was upwards of twenty years' duration. I have no doubt this disease was originally of a fibrous character. The calcareous matter and other changes resemble those occasionally observed in large fibrous tumours of the uterus. A tumour of a similar character and of great size was removed by operation from the scrotum of a man in St. Vincent's hospital, Dublin, by Dr. O'Ferrall.*

THORAX (θώραξ from θορέω to leap, because in it the heart beats). "The habitation of the breathing parts." — That part of the human body destined to contain the lungs and heart, and by its movements to maintain the function of respiration.

Generally by the term *thorax* is understood a cavity set apart for the respiratory organs. Such a cavity, however, is not essential to respiration: a respiratory surface only is essential. This must exist in every animal, whilst a separate thorax is found perfect only in mammalia.

The development of the respiratory surface may take place in three ways.

1st. Either towards the *interior* of the body, in the form of ramified or sacculated cavities; or,

2ndly. Towards the *exterior*, in the form of lamellated, ramified, pectinated, tufted, ciliated, or pinnated processes called "*branchiæ*," in which Nature seems to have exhausted all imaginable varieties of form; and,

3rdly. By a system of tubes ramified to extreme fineness, either in an especial cavity or thorax, or in a cavity common to these organs and to others destined for the digestive function.

The movements necessary to respiration, are modified according to the form of the respiratory apparatus and the nature of the medium to be respired, whether pure air or air contained in water.

In some of the lowest animals, the respiratory movements are the same as those of locomotion, as in the monad and other infusorial animalcules. In all animals, even when the respiratory organs are contained in a true thoracic cavity, the frame-work serves other purposes besides that of drawing in and throwing out air; it gives attachment to the largest muscles of the upper extremity, whether prehensile or locomotive. In man particularly, we find the respiratory muscles contribute to such acts as coughing, sucking, sneezing, yawning, sighing, singing, vomiting, as well as the innumerable articulate sounds of language.

Distinct respiratory movements, as dependent upon alternate contractions and dilatations of a thoracic cavity, are most regular, or at least, they have been more noticed, in mammiferous animals. The thoracic cavities of mammiferous animals have much of the mechanism of respiration in common. They all possess a vertebral column or spine, and that peculiar frame-work of ribs, together with a sternum, so articulated together as to move in breathing.

There is likewise a great similarity of muscular arrangement around the thoracic cavity; and consequently the respiratory movements closely resemble each other.

Although the boundaries of the thorax are generally the parts which move in respiration, and these are generally composed of vertebræ ribs and sternum, yet some animals may have either all of these, or they may lack some of them, or, if present, they may not move in the breathing function. *Frogs* have a sternum, but no ribs; *serpents* have ribs, but no sternum; *tortoises* have ribs, vertebræ, and

* Dublin Hospital Gazette. Feb. 1845

sternum in one mass, rigid and immoveable: the *crocodile* and *lizard* have perfect ribs, but their sternum is almost entirely cartilaginous; and, lastly, in man, the components of the thoracic cavity may have a mobility to command or exceed a space equal to the whole cavity allotted for the respiratory organs. The relative quantity of air which he can respire for the aëration of his blood is probably greater than in any other animal, and his movements are more under the control of his will, and are greatly influenced by mental emotions.

Classification of the Respiratory Movements in Animals. — It is not easy to name any particular part in the perfect thorax of the higher vertebrata, which is equally destined for respiratory motion throughout the class. Commonly with ribs and intercostal muscles, we connect the idea of a thorax, or a breathing chamber for respiration; but a fish has ribs, and likewise intercostal muscles, yet not for any of the purposes of respiration, nor do we acknowledge them to belong to its thorax. A frog has a thorax for respiration with internal lungs, but no ribs, nor, consequently, any intercostal muscles. Nor is a diaphragm necessary to thoracic respiration; for it is mostly absent in birds and reptiles, and quite rudimentary in the few instances (such as the ostrich, crocodile, and chelonia), in which it is met with. In the chelonia neither ribs, spine, nor sternum are concerned in the respiratory movements.

The movements of respiration tend to bring before some surface, air or air contained in water; or to bring a certain surface continually into a fresh medium, In whatever way this may be accomplished, whether by moving the whole body, or part of the body to and fro, such movements, likewise, are not uniformly for the mere purpose of respiration, i. e. the mere purpose of aëration. All reptiles take more air into their capacious lungs than they require for oxygenating the blood, particularly in the aquatic kinds (as in the turtle), where the air serves to buoy up their heavy and slow-moving bodies in the dense element they inhabit. Serpents are provided with numerous highly-moveable ribs and powerful intercostal muscles, capable of rapid and extensive inspiration and expiration. They can perfectly distend their body with air. The same may be observed in the chameleon. These volumes of air cannot alone be subservient to respiration, as it cannot all come into contact with the simple undivided respiratory sacs. We see, therefore, there is no necessary relation between the quantity of air an animal may inspire and the extent of respiratory surface. The long hissing sound which serpents produce to alarm their prey, is effected by the expulsion of this great volume of air, by their ribs, through the narrow passages of the nostrils.

In the higher mammiferous animals, we find respiration more especially destined for the chemical purpose of oxygenating the blood. Hence a more limited quantity is taken in, and it is speedily thrown out again. Large animals make fewer respirations than small ones. According to Scoresby*, the whale breathes four or five times a minute; the dog, the cat, and rabbit, from twenty to thirty in the same period; and in small birds the respirations are remarkably rapid.

Whatever be the form of the aërating organ, "breathing" is accomplished either by, 1st, the weight of the atmosphere rushing into certain cavities, because certain parts of these cavities dilate and threaten a vacuum; or, 2ndly, by the direct projectile or collapsing force of an organ *throwing* the ambient element onward. These two ways are generally more or less combined in the same animal. Nor does there appear to be any relation between the grade of the animal and the order of respiratory movement obtained. We notice in the respiration of man a regular inspiration and expiration, two currents in different directions; and in the lowest animal, the connecting link with the vegetable kingdom, the porifera, or sponge tribe, there are likewise two respiratory currents by distinct channels, which are as regular as the motion of rivers from their source to the ocean, or any other movement depending upon the established order of things. In some species of medusæ, there are peculiar sacs on the inferior surface of the body, which, during the expansion of the body, admit water through certain apertures, and again expel it during the succeeding contraction, representiug a perfect inspiratory and expiratory action. The complexity, therefore, of respiratory movements does not correspond with the increasing development of the breathing organs. Those animals which have an internal sacculated lung, always retain a certain quantity of the breathing element in "*reserve*" within their system; whereas those animals which have external lungs, or gills, have no "*reserve*" respirable medium. They need none, because where there is an external lung, the ambient element answers the purpose of the "*reserve*"; it is always in contact with the breathing surface. This "reserve," in mammalia, &c., is not, probably, so necessary to aëration as for the purpose of ejecting any matter which may obstruct the air passages — or, in more popular language, for "coughing" up any matter out of the throat.

The different kinds of respiratory movement may be arranged as follows; —

1. Infusorial Animalcules	By projectile force.
2. Insects - - -	Uncertain.
3. Fishes - - -	By vacuum & projectile force.
4. Amphibia - -	do. do.
5. Birds - - -	do. do.
6. Mammalia - -	do. do.

Of the First Kind of Respiratory Movement. Infusoria.— These animals breathe by a stream propelled in one direction, produced by the ra-

* El. Physiol. Wagner, 8vo. 1844, p. 670.

pid vibration of hair-like organs — cilia. (Vid. Art. CILIA.)

Of the Second Species of Respiration. Insects.— The breathing apparatus in insects generally reaches a high degree of development. Sometimes respiratory tubes or tracheæ penetrate every part, in the form of minute ramifying vessels conveying the included air to all the organs. The moving power or means of the renewal of the air in these tubes is at present little known. Some insects, although they live in water (as, for instance, the water beetles, and also water spiders), retain a bubble of air around them ; and, according to Nitzch*, they renew the air in the irtrachæ by alternately elevating and depressing the antennæ. Beetles, before flying, seem to *inflate* themselves with air, so as to unfold their wings, which, like other parts of their body, are supplied with air tubes. In this case an inspirative effort must be made by some cavity. Under certain circumstances, bees emit a voice, a shrill sound, which is independent of the motion of the wings, and which appears to be connected with the existence of a current of air through the respiratory tubes or tracheæ; at least, such has been observed when the animal has been irritated and immersed in water, the surface of which, where it was in contact with the orifice of the stigmata at the root of the wing, evidently vibrated at the moment the sound was produced.†

In the *orthoptera* particularly, there are distinct respiratory movements, alternate dilatations and contractions of the abdomen ; in fact, respiratory motions are more distinctly perceptible in this division than in any other insects. In the *locusta verrucivora* particularly, it is easy to distinguish how the abdominal rings, which have smaller abdominal scuta between them inferiorly, are alternately *elevated* and *depressed* exactly like ribs. If we smear the great thoracic stigmata with oil, we find that numerous bubbles of air escape from it during these motions.

The organs of respiratory motion, by means of which the supply of air is renewed, present many points of uncertainty. On the one hand, where large stigmata are placed opposite to each other, and connected by tracheæ, it is easy to see that alternate opening and shutting of their valves may produce a current capable of renewing the supply of air. It is conceivable also, how, in the orthoptera, lepidoptera, and others, the expansion and contraction of the body, and the elasticity of the air-sacs contained in it, may cause the ingress of air. It is less obvious, however, how the same effect is produced in caterpillars and the larvæ of beetles, where a current of air cannot very easily arise from the opposite position of the stigmata, on account of the minute ramifications of the tracheæ ; and consequently we must look for some peculiar mechanism, probably cilia, unless we are disposed to admit the stagnation of the air in its vessels. Hence it has been conjectured that the dilatation and contraction of the dorsal vessel contributes to this purpose. This, however, appears to be scarcely possible ; and it might be asked on the contrary, if the vermicular motion of the body itself, the sliding of its segments upon each other, are not the means of keeping up the constant ingress and egress of air.*

In the lowest of the molluscous class, the external tunic with which they are covered is generally so elastic, that it is capable of dilating by its own properties, when it has been greatly contracted by the muscular coat that is within; and in forcible expirations, Dr. Grant has observed these animals to contract their muscular coat, and to retract the exterior covering, so as to propel, with considerable impetuosity, and to a distance, the water that fills their respiratory cavity. The elasticity of the tunic tends to overcome the resistance of the muscular coat, and to expand, to a certain extent, the respiratory cavity. Without, therefore, the existence of elastic ligaments, such as we find in conchifera, there is a partial means of enlarging the respiratory cavity given to these tunicated animals. This, however, is only in occasional, forced, respiration ; constant and alternate contraction and expansion of the exterior tunic is not met with in any known tunicated, nor in a conchiferous animal.† The streams that enter the respiratory, and pass out of the anal aperture, are smooth, regular, and incessant, and are produced by ciliary movement.

Of the Third Species of Respiration. Fishes. — It may be said that the thorax of fishes usually presents four elastic cartilaginous arches, which *approximate* and *separate*, open or close the gills, at the same time *increasing* or *diminishing* the capacity of the so-formed thorax. These ribs, or branchial arches, support the gills, which are covered by a great flap (operculum) on each side of the base of the skull.

The respiratory current enters at the mouth, passes through the fissures on each side of the fauces, and escapes through the branchial openings, placed laterally, covered by the moveable operculum. This stream is uniformly in one direction, — from before, backwards. It might be asked, why does not the water rush in by the branchial opening when the mouth "threatens" a vacuum ? It will be observed that the margin of the operculum, or great lateral flap, is edged with a delicate membrane, which acts as a valve, this, by the pressure of the water, is forced close round the lateral openings : thus, the water, upon the expansion of the jaws, is prevented entering behind, and consequently rushes in towards the gills by the mouth ; the jaws now close, the operculum immediately opens by the

† Grant's Lecture "On the Respiratory Organs of Invertebrata." Lancet, 1833—4, vol. i. p. 964.

force of the jaws contracting with the mouth full of water, which contraction, or expiration, forces the water through the branchial arches and ultimately out by the lateral openings.

Thus the respiration is of a mixed order. The first stage by atmospheric and hydraulic pressure; the second stage by direct muscular force, similar to that of swallowing.

If we cut off the delicate fringe around the operculum the fish is suffocated, the operation being analogous to puncturing the human thorax.

Fishes also possess a power of regulating their respiration. We have watched fishes when in a quiescent state move their respiratory organs so gently that the motion was nearly imperceptible, and at times quite so; but if at such times you alarm the animal, respiration becomes vigorous, and a comparatively vast body of water rushes past their respiratory organs. The same may be likewise observed when fishes have remained long in a small quantity of water, as if the respiratory movements became more and more vigorous with the deterioration of their element, but give them a fresh supply of water and respiration becomes quiescent again.

Of the Fourth Species of Respiration. Amphibia.— In this class there is a gradual development of the animal formation from an aquatic to an aërial being; so likewise is the aqueous gradually converted into aërial respiration.

The respiration of some of these animals is indeed most curious, — curious as to the very limited quantity of air necessary for their well-being, and curious as to whether they have this limited quantity supplied regularly or otherwise. For instance, you may keep an aquatic turtle out of water for days, and it will keep constantly respiring air; immerse it in water, and it will remain below the surface for half an hour, or an hour, without any inconvenience, and some of these animals will breathe at the surface during the day, and sleep at the bottom *all* night without once rising for air, while during the day the same animal cannot remain below above half an hour without showing signs of discomfort. And again, the common tortoise during hybernation breathes so small a quantity of air, that we have never been able to form any calculation of the quantity then respired.

In frogs there are no ribs by which the lungs may be moved; consequently there is no vacuum formed by their thorax during respiration; they fill the lungs like the tortoise, the newt, the chameleon, &c., by the working of their jaws; or, in other words, they swallow their air just as we swallow our food. In this respect their respiratory movements resemble those of fishes; the first process being through the agency of external pressure, by making a vacuum with the mouth; the second, that of *forcing*, by the operation of the pharynx. They resemble mammalia in having an internal lung, retaining the air for some time, and in expelling it through the same channel by which it entered. The respiration of the frog has gained attention, and is hence better understood than that of many other animals of this class. The following is the mechanism of its respiration, as described particularly by Townson *, though before noticed by Swammerdam and Malpighi. When the broad lingual bone which forms the floor of the mouth is drawn down from the palate by its muscles, the air of the mouth is rarefied, and an additional quantity enters by the nasal apertures, which admit of being closed by valves. The lingual bone is then raised, the nasal apertures are closed, and the air is now *forced*, or rather swallowed, through the rima glottidis into the pulmonary sacs, and can also fill the laryngeal pouches which open into the mouth. Expiration is produced partly by the pressure of the abdominal muscles, and partly by the peculiar muscular power of the pulmonary parietes. To the careless observer the frog does not appear to breathe: it is never seen to open its mouth; there is no motion of its sides like breathing, and when it is provoked (or rather through fear), though it still keeps its mouth close shut, its sides and back rise, and it blows itself up apparently by some internal power. Upon observing it more narrowly, that skinny and bag-like part of its mouth which is under the jaw, is seen to be in constant motion. While this bag is dilating and contracting, the mouth is *never* opened to take in new air, but it seems to live all the while on one mouthful of air, and seems to be playing it backwards and forwards between the mouth and lungs. If we now observe the nostrils, a twirling motion, which lets in air at each movement of the jaws, is apparent, corresponding to the quantity of air inspired. If we keep the mouth open we presently see the animal struggle for breath, for we by this means disable the forcing apparatus from propelling the required air into the lungs.

The newt breathes with the jaws and nostrils like the frog. It has, like the frog, a constant motion, by short strokes of the bag under the jaw. This bag is formed by the membranes of the mouth, covered and moved by the genio-hyoid and mylo-hyoid muscles. Every minute, or less, it stops, as if intending some particular motion; then gradually the bag swells out under the lower jaw to a great size; the contained air is then pressed down into the lungs, and in proportion as the jaws are emptied, the sides of the animal are swelled up. The toad, the chameleon, and the green lizard breathe in the same way, *propelling* mouthfuls of air down into the lungs. The chameleon can force down a greater or smaller quantity of air, as its needs or fears prompt it. At times it seems to fill its body almost to bursting with air. The tortoise, like the frog, holds its jaws close, and swallows the air; alternately depressing and elevating the hyoid bone. The first of these motions permits the air to enter the nostrils, when, the tongue immediately closing their internal aperture, the second motion forces the air into the lungs. It is not un-

* Tracts and Obs. on Nat. Hist., &c. London, 1799.

common to notice tortoises yawn; but how different is their yawning from that of man, who makes, at that time, a deep inspiration, while, in the tortoise, respiration is impossible. We are not prepared exactly to say how the tortoise and turtle expire; but probably the expiration is performed by the contraction of the abdominal muscles between the lower shield or plastron and the posterior extremities; for either of these animals can at will, when alarmed, forcibly expel air with a hissing sound, although its shell is unyielding.

The most remarkable respiratory movement we have noticed, has been in the common turtle. Sometimes this animal will swell out his hard case, the sternum or plastron yielding to some internal force; but it is difficult to say by what means this is distended and *kept distended.*

It is clear this animal can gorge itself with air until it cannot sink in water, and that at pleasure it can disgorge itself and fall to the bottom, where it lives upon only a fraction of the quantity of air it had just previously expelled.

Of the Fifth Species of Respiration. Birds.—Here we have a contracting and dilating thorax, with ribs and sternum. The cavity of the chest is not divided by a diaphragm, but is common to the whole digestive organs as well as the lungs; or, as is said, they are "all chest and no belly." They differ from all other animals in this respect, that the lungs do not hang in the cavity of the trunk as unattached sacs, but are attached in the form of flattened masses, of spongy, bright red, cellular texture, to the posterior side of the thorax, reaching to the pelvis. They have vesicles or âir bags extending through the whole body; and the cancellated structure of their bones is connected with the true lungs; so that if we tie the trachea and amputate the wing, leaving the stump of the bone exposed, the bird can inspire and expire through the humerus. In the same manner that the diffusion of air through all parts of the body in insects makes the highest extent of respiration in invertebrata, so also is it with birds among the vertebrata.

The sternum and ribs, together with the immoveable range of dorsal vertebræ, all contribute to dilate and narrow the thorax, after the manner of a bellows movement. This dilatation and contraction draws the air *through* the true lungs, which never move, and immediately the air cells are expanded. By this means two conditions are obtained; the air is drawn through the lungs for aëration; and the air filling the cancellated structure, renders the bird specifically lighter.

The high flying rapacious bird can thus by a respiratory movement attenuate the air in his body, when soaring in the atmosphere, and again at pleasure condense it in every interstice of his frame, when he drops like a cannon ball, to pounce on his prey; but immediately before seizing it, again he attenuates the air within him to break his fall; otherwise he would be dashed to pieces upon the pointed crag, and die along with his victim.

This beautiful provision is wholly due to his respiratory movement, at one time acting as a condensing, and at another time as an exhausting syringe.

Of the Sixth Species of Respiration. Mammalia.—In this class we first meet with a perfect muscular septum (diaphragm) forming the two cavities of the trunk; the one for the lungs, and the other for the abdominal viscera. All animals which have a diaphragm, maintain respiration in a manner similar to each other; for, indeed, it appears that the only use of this muscle is to maintain a movement of air —that unceasing pumping to and fro of inspiration and expiration. Their respiration, or at least their *inspiration*, is purely of the vacuum order.

The diaphragm is the chief muscle of ordinary breathing. It can act with great power, protruding the viscera, by its descent, at each ordinary inspiration. This is strikingly seen in animals recumbent and at rest, as in the cow, horse, goat, dog, &c., when it appears, as if the animal was breathing with its abdomen. The ribs likewise in some degree maintain respiration in the lower mammiferous animals, particularly in disease. For instance, the respiration of the horse or dog, when the lung is emphysematous, or what is familiarly termed "broken-winded," is costal, and at such times the respiratory action of the ribs may be beautifully seen.

It is most probable that in mammalian respiration we have the highest order of *accommodation* for peculiar respiration, according to the condition of the animal; i. e. an instinctive power to respire by different parts of the thoracic cavity, according to the needs of the animal, whether modified by health or disease.

Nearly two hundred years ago, Lower changed the respiratory movements of the dog from diaphragmatic to costal, by paralysing the diaphragm through the medium of the phrenic nerve. (*Phil. Tr. Abr.*, vol. i. p. 179.)

The respiration of mammalia is the bellows action — inflation of the lungs by expansion of the thorax, or inspiration by vacuum, and expiration by propulsion.

The projectile force in the respiration of mammalia is nearly all due to mere elastic contractility; i. e. ordinary expirations are produced by the elasticity of the lungs and ribs, returning backwards, or collapsing, after their distension by the inspiratory muscles. This mere dead and involuntary force performs one half of our respiration.

Man is not distinguished either by the force, extent, or complexity of his respiratory movements; he is exceeded in all these particulars by inferior animals. The roar of the lion gives the idea of an overwhelming expiratory power; nor are his lungs less complicated; and the vibration of thousands of cilia, promoting currents around the monad, is more complex than the simple respiratory thoracic action of mammalia. The most striking difference is that produced by mental influence, which appears to command the most delicate modifications of this movement, so indicative of the passions of his mind, while in the lower animals we see none of these.

Of the Thorax in Man. *Anatomy of the framework of the Thorax.*—A portion of the spine, the ribs, the sternum, together with numerous muscles, form the wall of the human thorax. The framework of bones is so arranged as to admit of free mobility in various directions, so as to increase or diminish the cubic capacity of the thoracic cavity.

Of the Dorsal Vertebræ.—That portion of the spine which enters into the composition of the thorax consists of the dorsal vertebræ, which are 12 in number, intermediate in size and position, between the cervical and the lumbar vertebræ. They form the main pillar of support for the whole respiratory apparatus —the great fixed point for the chief respiratory muscles to act against or draw upon. Their general appearance is that of increasing in size from above downwards; but when carefully examined, they are as two cones, the apices of which touch at about the fourth or fifth vertebra, from which point, in either direction, they increase in their dimensions; their breadth laterally exceeds their depth from before backwards. Their bodies are large and project deeply into the cavity of the thorax, diminishing greatly the antero-posterior diameter of the chest. Out of twenty cases, the average projection is $2\frac{3}{8}$ of an inch, leaving little more than 4 inches for the heart and great blood-vessels.

A deep sulcus is thus formed, which if a cast be taken of the cavity of the thorax, is very striking. In phthisis pulmonalis, the space between the bodies of these vertebræ *and the sternum* is sometimes *less* than one inch! When the thorax changes its form by disease, this centre pillar is liable to wedge in or jam up the thoracic organs against the walls of the chest.

The vertebræ are connected to each other by ligaments, and jointed beautifully into each other, so as collectively to admit of extensive motion, while there is but little movement between any two vertebræ.

Of the bonds of union, the most remarkable are the *inter-vertebral disks* (*ligamenta inter-vertebralia*—Weitbr.)—composed of fibro-cartilage, and placed between the bodies of the vertebræ, each disk serving to unite two vertebræ, and yet to permit a motion in any direction, yielding on that side towards which the column inclines, while on the contrary side it expands with the increasing intervertebral space. This substance is to the brain what the cushion or "buffer" between each railway carriage is to the traveller; it breaks a sudden jar from being transmitted from carriage to carriage. So does this intervertebral substance soften down any sudden jerk received at the lower extremity of the spine, preventing its being transmitted to the brain in the varied actions of walking, running, and leaping.

Of the Sternum (*os pectoris: Xiphoides*), so named from στέρνον, the breast: is a kind of flattened bone, symmetrical in shape, which occupies the anterior and middle part of the thorax. It is supported by the ribs on either side; it is broadest at its upper part, and then narrowed; it widens again, and finally becomes compressed and narrow where it joins the ensiform cartilage. (*Fig.* 660, *e.*) Its direction is oblique from above downwards and forwards. This, with the curvature backwards of the spine opposite to it, increases the antero-posterior diameter of the thorax, as may be seen in a lateral view of a cast of the thoracic cavity.

The length of the sternum, which is proportionably smaller in the female than the male, varies from 5 to $7\frac{1}{2}$ inches. At the upper part its breadth is from $1\frac{1}{2}$ to 2 inches.

Its thickness above is about 6 lines; at its lowest part it is much thinner, never exceeding three lines. The ancients compared the sternum to the sword of a gladiator; and hence have arisen the denominations given to its various parts: as the handle (*manubrium*), the body (*mucro*), the point, or xiphoid appendix, (*ensiformis*); but the last mentioned part now only retains the designation grounded on this circumstance. This division of the bone into three parts has been retained by some modern anatomists, who describe the three pieces of the sternum separately, as so many distinct bones; we shall only adhere to this in speaking of the development of the bone.

In anatomical language it is said, the sternum presents two surfaces, two borders, and two extremities.

Of the anterior or cutaneous surface of the Sternum.—This is subcutaneous, slightly convex and affords attachment to the aponeurosis of the pectoralis major and the sterno-cleido-mastoid muscles. It presents three or four transverse projecting lines, which are traces of the original division of the bone into five pieces. The union between the 1st and 2nd pieces corresponds to the insertion of the 2nd costal cartilage, and is frequently cartilaginous even in the adult age. The line which marks the union of the first two pieces of the bone is the most remarkable: it causes a projection of variable size in different individuals, which has been sometimes mistaken for a fracture or exostosis. At the lower part we sometimes find a *foramen;* sometimes in place of the foramen there is a considerable aperture, to which much importance has been attached, as affording a proof of the primitive separation of the bone in the median line. (*Fig.* 660. *d.*) The existence of this opening explains how purulent matter deposited behind the sternum may, in certain cases, make its way outwards without any absorption of the bone. This bone is covered by a strong interlacement of very numerous aponeurotic fibres.

Of the posterior (*mediastinal or cardiac*) *surface.*—This is slightly concave, and parallel in direction to the anterior surface. The concavity is directed downwards and backwards, towards the cavity of the thorax, and gives attachment superiorly to the *sterno-hyoideus* and *sterno-thyroideus* muscles, inferiorly to the *triangularis sterni.*

Along the middle line, this concavity corresponds with the interval left by the divergence of the two pleuræ (anterior mediastinum).

In the young subject, transverse lines are seen corresponding to those which occupy the anterior surface; all of these, except the two between the first and second pieces of the bone, are effaced at a more advanced age. This surface is in relation with many organs contained in the chest, and especially the heart, in front of which the sternum forms a kind of shield. This is exemplified, as already noticed, in the *frog*, which is provided with a sternum, though it has no ribs. At the lower part of the sternum are many nutritient foramina.

Of the borders of the Sternum. — These are thick and marked at each side by seven angular depressions for the reception of the cartilages of the first seven ribs, which gives this bone a notched and serrated appearance. These angular cavities are separated from each other by semilunar notches, which are longer above than below, where the facettes closely approach each other. The uppermost of these seven cavities is shallow, triangular, and at an early age becomes ingrained with the cartilage of the first rib; those which follow are deeper, angular, and situated at the extremities of each of the transverse lines. When examined in the dried specimen, they appear more angular and deeper in proportion to the youth of the subject.

Of the clavicular extremity.—This is slightly convex, and is the broadest and thickest part of the whole bone. It is slightly excavated from side to side, and presents at each corner a depression for the reception of the sternal end of the clavicle, which bears the name *fourchette;* this is surrounded with irregularities for the insertion of ligaments. It frequently happens that the two clavicular articulations are not at the same height; a fact which was noticed by Morgagni, and which Cruveilhier attributes to the unequal wearing of the two articular surfaces. We have once seen the clavicular articulation so low as to unite with the first costal cartilage.

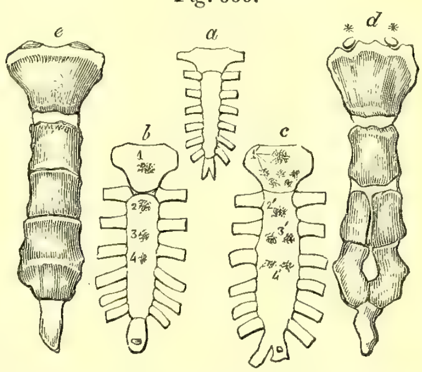
Of the inferior extremity of the Sternum. — This is formed by the *xiphoid* appendix; or *ensiform* cartilage, for it often remains cartilaginous to adult age. In length, shape, and direction, it presents numerous varieties; it is frequently bifid, sometimes pierced by a foramen, and is occasionally bent forwards, or to one side, and in certain cases much depressed: its summit gives attachment to an aponeurotic structure, called the *linea alba;* behind, it indirectly corresponds with the stomach, which rests upon it when the body is placed in a prone position.

Connections. — The sternum articulates with fourteen ribs through the medium of their cartilages, and more directly with the two clavicles.

Structure of the Sternum. — This bone consists of two very thin compact laminæ, with an intervening cancellated structure, the cells of which are very large and have very delicate parietes. It is one of the most spongy bones of the body, and it is more than probable that to this circumstance the frequency of disease in it may be attributed. Absorption of this bone and great displacement by bending inwards is very common, particularly in women who wear tight stays. Under such circumstances, or by disease, we have witnessed the sternum so depressed inwards that the depth, including all the thoracic integuments from the spinous processes of the dorsal vertebræ to the anterior surface of this bone, did not exceed three inches, instead of from seven to nine inches.

Of the Development or Ossification of the Sternum. — As far as the middle of fœtal life or a little later, the sternum is altogether cartilaginous, as represented at *a*, *fig.* 660. This

Fig. 660.



bone is one of the slowest in its ossification; it exhibits no bony points or centres of ossification up to the sixth month of fœtal life. It is also of all bones the one in which the phenomena of ossification proceed with the least regularity. After the sixth month of fœtal life, ossification begins with the formation of osseous granules in the middle of the intervals between the points at which the cartilages of the ribs are connected.

"There are five of these granules for the sternum, exclusive of the ensiform appendage, and they form as many pieces (*e*, *fig.* 660.). The process of ossification makes its appearance in the first between the fifth and sixth months; and, soon following in the second and third, it reaches the fourth at the end of fœtal life. The osseous centre of the last varies considerably in the time of its appearance. It may be found soon after birth, and may not be visible for a considerable time (one or two years) after that period."

"In many cases, one or more of the divisions of the sternum are formed from more nuclei than one, and there are peculiarities with respect to the number and position of these additional granules which require notice."

Ossification of the 1st piece.—This sometimes presents a single nucleus (*fig.* 660, *b* 1.), rounded and transversely strong; sometimes it presents two nuclei, and in this case they may be either placed one above the other, or side by side. In the former case the uppermost nucleus is the larger; in the latter, both may be symmetrical and of equal size, or what is more common, they may be of unequal magnitude. It may occasionally present more than two osseous points. Albinus found three in one subject, and four in another.* Mr. Quain has a preparation in University College, where the very unusual number of six (*fig.* 660. *c.* 1′.) are to be seen. In this case, where there is a plurality of osseous points, the largest are generally situated alone; exceptions to this rule are very rare.

Ossification of the body, or the 2nd, 3rd, 4th, and 5th pieces.— The osseous nuclei which enter into the composition of the body of the sternum have generally a rounded form when they are single, and are situated in the middle line; where they are in pairs or are placed laterally, they are more elongated, but smaller, and appear to represent only the half of one of the single nodules. The second piece has not often more than a single granule (*b.* 2, *c.* 2′.), but the rest are frequently formed from two nuclei, which are placed laterally to one another (*c* 3′, 4′.), and not vertically as occurs in the first piece.

These different osseous points are always so arranged as to be situated between two costo-sternal articulations, so that a portion of the sternum is developed in each of the intervals comprised between the ribs. The last piece is the only exception, being common to the articulation of the 6th and 7th ribs. There are, therefore, four primitive pieces of the body of the sternum (*b.* 1, 2, 3, 4.), and each of these is sometimes formed by one point of ossification; at other times by two lateral points. The first piece may be formed of one or many ossific points, which may be arranged vertically as well as laterally To the centres of ossification here described, M. Brechet † has added two small epi-sternal granules, whose position is sufficiently shown by the indication of them, *fig.* 660. at *d***. They occur only at rather advanced periods of life, but they do not appear to be constant.

Union of the points of ossification of the body of the Sternum.—In considering the union of the different parts which compose the body of the sternum, it is necessary to make a distinction between the *lateral* conjunction—that is, the union of the osseous points which are situated on each side of the median line—and the *vertical* conjunction, or the union of the pieces of the sternum properly so called. The *lateral* conjunction, or the union of these osseous germs, which form a pair in the same interval, always precedes the *vertical* conjunction.

The *vertical* conjunction, or the union of the different pieces of the body of the sternum together, commences with the two inferior portions. After this union, the body of the bone consists only of three parts. The 2nd piece then unites with the lower: the sternal foramen is formed sometimes at the junction of these last mentioned parts, sometimes at the place where the two lateral points of the 4th and of the 3rd portions of the body are united. If the interruption to the progress of ossification should occur at the point where the lateral parts of two sternal pieces would meet, the foramen is likely to have considerable size; for it may be the result of an "arrest of development" proceeding from four centres each constituting a part. (*Fig.* 660. *d.*) The union of the divisions of the body of the sternum takes place precisely in the inverse order of their appearance In fact the appearance of the osseous points proceeds from above downwards, while their union proceeds from below upwards: a fact which verifies the assertion, that the order of development of osseous points is not always correlative to the order of junction.

The lowest or 5th piece is joined to the 4th soon after puberty; the 4th and the 3rd are united, between 20 and 30 years of age; and the body of the sternum is usually not completed by the junction of the 3rd piece to the 2nd before 35 or 40 years. Lastly, the 1st division does not in general join the rest of the sternum at any period; but should its union happen to take place, it is only to be met with in advanced age.

Of the ossification of the appendix.—This is generally accomplished by one nodule. Sometimes there are two; and then they are rarely symmetrical. The process commences in the upper part of the cartilage, and very rarely extends through the whole. The time of appearance of the osseous point is extremely variable. Sometimes it is visible towards the 3rd or 4th year; sometimes not until the 12th or even the 18th year; according to the observation of Béclard, between the 2nd and 18th years.

From the 40th to the 50th year, and sometimes later, the appendix becomes united to the body of the sternum. From the varieties of ossification or development of the sternum, it will be evident that it is impossible to assign to it a limited number of osseous points.

Of the Ribs.— The ribs (*Costæ* from *custodes* *) extend from the dorsal portion of the vertebral column to the sternum, forming arches which correspond to the lateral segments of the chest. About one sixth of the ribs are cartilaginous, and the rest osseous. The osseous portion is the *rib* properly so called; the cartilaginous portion is named the *costal cartilage*.

The ribs are 24 in number, 12 on each side; but cases occasionally occur in which this number is augmented by the addition

* Cruveilhier, Descrip. Anat. 8vo. 1840. Lond. p. 87.

† Recherches sur Différentes Piéces du Squelette des Animaux Vertébrés, &c. in "Annales des Sciences Naturelles." 2de Serie, t. 10. (Zoologie) p. 91.

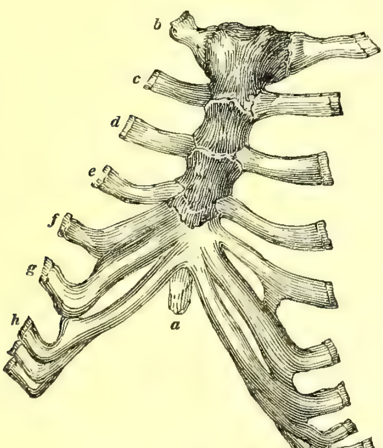
* As if they were guardians of those principal organs of the animal machine, the heart and lungs. —Munro: The Anatomy of the Human Bones. p. 234. Edingb. 1726.

of a pair of cervical or lumbar ribs: in this case the supernumerary ribs are formed from the anterior parts of the transverse processes of either the seventh cervical or first lumbar vertebra; which affords a strong proof of the analogy existing between a transverse process and a rib. Sometimes the usual number is diminished to 22: this is more rarely the case. When this occurs, we sometimes find two adjacent ribs united throughout their entire length. Sometimes the first rib is in a rudimentary state, being properly formed posteriorly, but having its anterior extremity lost among the muscles, or united to the 2nd rib. Mr. Quain has lately seen an instance in which this diminution of the number of the ribs was accompanied with the absence of a dorsal vertebra.*

Classification of the ribs.— The ribs are numerically designated 1st, 2nd, 3rd, and so on, counting from above downwards. In the living or in the undissected subject it is easier to count the ribs from below upwards.

The seven superior ribs are united by means of their own cartilaginous prolongations (*fig.* 661. *b*, *c*, *d*, *e*, *f*, *g*, and *h*; and *fig.* 662.)

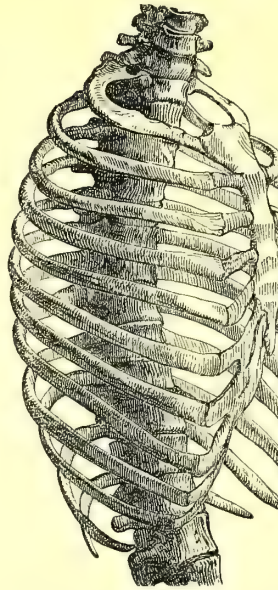
Fig. 661.



to the sternum, and are called *true ribs* or *sternal ribs*, or *vertebro-sternal ribs*; the remaining five are not so immediately prolonged to the sternum, and are denominated *false ribs*, or *asternal ribs*, or *vertebral ribs*.

We think it would be more judicious to classify them otherwise, and consider the *five* superior ribs as *sternal*, *true*, or *thoracic ribs*; the *five* next inferior, as *diaphragmatic ribs*; the *two* last, being *floating* or *false ribs*. Because, the first five especially encompass the cavity of the thorax; the five next a portion only of this space, together with a large portion of the abdominal viscera; and, lastly, because the two last do not touch the sternum through the medium of any cartilage. The transverse shade (*fig.* 682.) represents the arch of the diaphragm, or the floor of the thorax. Every rib articulates with the dorsal vertebræ;

Fig. 662.



Position of the ribs and spine after deep expiration.

the spine is their fixed point, or centre of motion,— the main pillar upon which they act. The superior ten ribs articulate through the medium of cartilages, the first seven through the medium of their own, the next three through that of those of their superior neighbours, (*fig.* 661.) with the sternum.

The ribs have certain *general* characters which distinguish them from all other bones; and likewise certain *proper* or *special* characters, by which one is known from another.

I. *Of the general characters of the ribs.*—The ribs resemble flattened bony hoops, varying in breadth from ·4 to ·7 of an inch, and from ·1 to ·4 of an inch in thickness; they once attain a maximum, and twice a minimum length (*fig.* 662.)

They are of a very irregular shape. Their arch or curve is neither uniform relatively to each other, nor yet relatively to itself at different parts of the bone; moreover they are twisted in different degrees upon themselves so that the two extremities of the same bone point in different directions, and cannot simultaneously touch an horizontal surface.

Surfaces. — These bones present two surfaces: an *external* or *cutaneous* surface, which is convex and smooth; and an *internal* or *pulmonary* surface, which is concave and likewise smooth. The anterior end is comparatively flat, the posterior is more cylindrical and truncated, and is rough, particularly at the extremity.

Borders. — The ribs have two borders, the one superior, and the other inferior. The superior border is smooth and rounded, and gives attachment to the intercostal muscles;

* Elements of Anatomy by Mr. Quain and W. Sharpey, M.D. London, 8vo. 1843, p. 105.

the inferior border is more thin and sharp, particularly in the middle third, or body, of the bone. This thin or blade-like appearance is caused by a groove on its inner aspect termed *sulcus costalis*, which is commonly said to be for the lodgment of the intercostal vessels: this border also gives attachment to the intercostal muscles. The borders are irregular in their direction corresponding with the shape of the rib; which we shall presently notice.

Fig. 663.

Fourth rib.

Extremities. — (a) Posterior or vertebral extremity. (*fig.* 663. *c*). — This is rougher and somewhat thicker than the other parts of the rib, and is hence denominated its *head* (*capitulum costæ*). It presents, except in instances to be presently stated two articular facets, a superior and an inferior one, separated by a well-defined ridge. Each of these facets articulates with a corresponding small surface on the bodies of two vertebræ, the ridge just mentioned corresponding with the intervertebral substance.

The head of the rib is supported by a narrow round part, somewhat constricted — the *neck* (*fig.* 663. *f*). This is flattened from before backwards and is the weakest part of the bone. Behind the neck there are some inequalities, which correspond to the transverse process of the dorsal vertebra below, Externally to the neck is an eminence known as the *tubercle* of the rib (tuberosity, *tuberculum costæ*, *fig.* 663. *g*), which is smooth in one part for its articulation with the transverse process of the lower of the two vertebræ to which the head is connected, and rough in the other, which is posterior, and in some ribs superior to the above, for the insertion of the posterior costo-transverse ligament. The tubercles are most prominent in the four or five superior ribs. Anterior to the tubercle the rib suddenly bends forwards, leaving this part the most convex, making what is termed its *angle.* (*fig.* 663. *h*) The interval which separates the tuberosity from the angle, is the thickest, roundest, and strongest part of the bone.

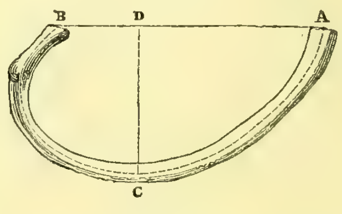
(b) Anterior, or sternal extremity (*fig.* 663. *d*). — The anterior extremity of the ribs is broad, flat, and deeply hollowed out at its tip into an oval pit, into which is implanted the costal cartilage. This extremity of the rib is broader and thicker than it is an inch more posteriorly.

Body. — This may be described as that part intervening between the angle and the anterior extremity. We have stated that the posterior end is more round than the anterior; the body, therefore, may be considered as of a transition form, passing from the cylindrical to the flat, blade-like, shape as it approaches towards the sternum.

Curve. — The curve which the ribs follow is very irregular, and therefore not easy to describe. No doubt they are of the form best adapted to admit of a great increase of thoracic capacity at the expense of a remarkably small movement. They appear to encompass the thorax in a somewhat spiral manner (see dark lines *figs.* 682 and 683.); to accomplish which they have three curves, one the common general arch or bend of the bone; the others the twist of the edges near the extremities termed the *curve of torsion.*

(A) *Arch or general bend of the ribs.* — This is the most remarkable feature of a rib. Whatever be the curve of the 1st rib, it may be said that each inferior rib describes a curve "one size" larger; so that one rib can be laid close within the other, like hoops of gradually increasing sizes. Two distinct curves will then be seen. It will be observed that the part extending between the head and the angle describes a larger circle than the angle itself, which as the name implies, is the most acute turn in the bone. More anterior to this, the curve becomes remarkably large; which Haller has so expressively described as representing the tangent to the posterior curve. In connexion with the general curve of the rib should be noticed two linear measurements, viz., the chord and the versed sine. In *fig.* 664. is given

Fig. 664.



Second rib.

the 2nd rib; the line A B is the chord, and D C the versed sine, or a line extending from the chord to the most prominent part of the bend of the bone. The general curve regulates the length of the versed sine.

This curve of the rib gives the sides of the chest a power of enlarging, — a lateral mobility, — according to the length of the versed sine, and quite distinct from the antero-posterior enlargement. which is according to the length of the chord. The ribs do not increase the lateral dimensions of the thorax by abduction, but solely by their rotation upon the line A B

(B) *Curves of torsion of the ribs.* — If we take the 7th rib and place it on a table it will be observed that the extremities cannot simultaneously rest upon one plane, because it is twisted upon itself. This is due to what is called the *curve of torsion.* The rib is twisted at each end; hence a posterior and an anterior torsion. The posterior torsion is most conspicuous, and is therefore more commonly noticed.

(*a*) Posterior torsion. — This torsion is marked at the angle of the rib (*h*, *fig.* 663.), particularly upon the convex surface, by an oblique line or a series of faint lines directed from above downwards and forwards. Like other features of the ribs, it passes through gradations, being scarcely perceptible in the 2nd rib, more so in the 3rd, and increasing to the maximum in the 8th, in the 9th and 10th it quickly decreases, until it is lost in the 11th and 12th. The greater the torsion the more distinct is the angle; where the angle is rudimentary the torsion is imperceptible, as in the 11th and 12th ribs.

The degrees of this torsion as it passes through the ribs are most distinctly seen by having the ribs separate, and placing them on a flat surface with their superior edge uppermost, arranging them so that they do not quite touch each other, when the heads of the different ribs will stand up at different heights from the table, forming a somewhat regular wave. This is solely produced by this posterior torsion.

(*b*) Anterior torsion. — Near the anterior extremity, on the convex surface, in well-developed ribs, we observe an oblique line analogous to that at the angle of the rib, but much less distinctly marked. This line may be considered as forming the anterior angle and corresponding torsion of the ribs, which, like the posterior, is intended for more favourable muscular insertions. Although the anterior angle is comparatively feebly marked, the anterior torsion of the ribs is as well defined as the posterior torsion. It will be seen in *fig.* 667, that while the posterior extremity of the rib curls *upwards*, the anterior extremity curls *downwards*. In like manner as we notice the posterior torsion by placing the separate ribs on a table, so may the anterior torsion be as strikingly seen, taking care to place the ribs upon their *superior edge* so that the sharp inferior edge is turned upwards. The anterior ends will be seen to stand up in different degrees from the table according to their torsion, commencing with the 3rd or 4th and terminating with the 10th rib.

Articulations of the ribs. — The ribs are articulated behind with the dorsal vertebræ, and in front with the sternum through the medium of the costal cartilages. This has already been noticed under *Extremities of the ribs.*

Position of the ribs. — The ribs are arranged more or less obliquely, — about midway between the perpendicular and horizontal (*figs.* 662. and 683.); — and they somewhat diverge from each other as they approach the sternum. (*figs.* 662. 680. and 681.) Not one of them is horizontal, though commonly represented as if they were. Their position is given in *fig.* 662. This is important to remember, because we shall see that costal breathing altogether depends upon their obliquity.

Structure. — The compact and spongy substances are so distributed throughout the whole length of the ribs that they possess a certain degree of flexibility, with great power of resistance. In young subjects the compact substance is in excess; in the aged, and in certain diseases, the opposite is the case; hence the extreme fragility of these bones, which are then broken by the least effort.

Development. — The ribs are amongst the earliest developed bones, ossification commencing in them even somewhat before it has made its appearance in the vertebræ. The deposition of osseous matter extends rapidly throughout them. Each rib (with exceptions to be noticed) is formed from one principal piece; and two epiphyses. Of these two epiphyses, one forms the head of the rib, and the other the tubercle: their ossification commences between the sixteenth and twentieth years of age; and they are united to the rest of the bone a few years after, — about the twenty-fifth year.

II. *Special characters of different ribs.*—The differential characters of the ribs, when minutely examined, are well marked; for, strictly speaking, no two ribs on the same side are of the same shape and dimensions. Although the difference is very small between two contiguous ribs, as, for instance, between the central ribs, *i. e.* between the 6th, 7th, and 8th, yet it is very conspicuous between those of the top compared with those of the bottom of the thorax. Whatever be the peculiarity under examination, we find it most developed in the 6th or 7th rib; and below this it becomes less and less marked, until, in the 12th rib, it appears rudimentary. In fact, the 12th rib may be considered little more than a prolonged transverse process; but not so with the 1st rib, which possesses all the marks and uses necessary to the character of a rib.

The ribs differ in their length, and in their chord and versed-sine measurements, and consequently in the area of thorax which they encompass. The thoracic dimensions vary considerably in different men and in the two sexes; yet the relative measurements and weight of the ribs will be found useful to our comprehending more perfectly the respiratory movements.

These relative measurememts are from a well-formed male thorax. The area-measurement is calculated from an internal cast of the thorax, cut up slice by slice through each intercostal space. These slices were traced upon paper and measured, giving the absolute area of thoracic cavity encompassed by each pair of ribs, their cartilages, and the sternum. (See *fig.* 668.)

Table A.—Relative Lengths and Weight of, and Area of Thoracic Space encompassed by, the respective Ribs, including the Space made up by the Sternum and Costal Cartilages.

Rib.	Absolute Length.	Chord Length.	Versed Sine	Area Sq. In.	Weight, Grains.
1	5·25	2·00	1·75	10·	98
2	9·00	3·75	3·00	27·	134
3	11·00	5·10	3·40	40·	181
4	12·25	6·00	3·50	51·	255
5	12·50	6·90	3·50	57·	308
6	12·60	7·10	3·50	63·	317
7	12·25	7·50	3·30	58·5	391
8	12·10	7·90	3·25	43·	363
9	11·50	7·75	3·10	27·	280
10	10·50	7·00	2·90	20·	216
11	8·25	5·90	2·25	10·	145
12	4·50	3·75	1·00	7·5	60

Fig. 665. represents the above table by curves. The perpendicular lines represent the ribs; and the curves the characters referred to. By a general view it will be seen that all the lines curve upwards, and are at their highest at about from the 5th to the 9th rib. We shall not treat of *particular* ribs, but of certain characteristics as they run through the ribs. A knowledge of their shape is necessary to comprehending the respiratory movements in diagnosing thoracic disease.

1. *Length.* — The length of a rib may be taken in three ways, — its absolute length, chord length, and versed-sine length.

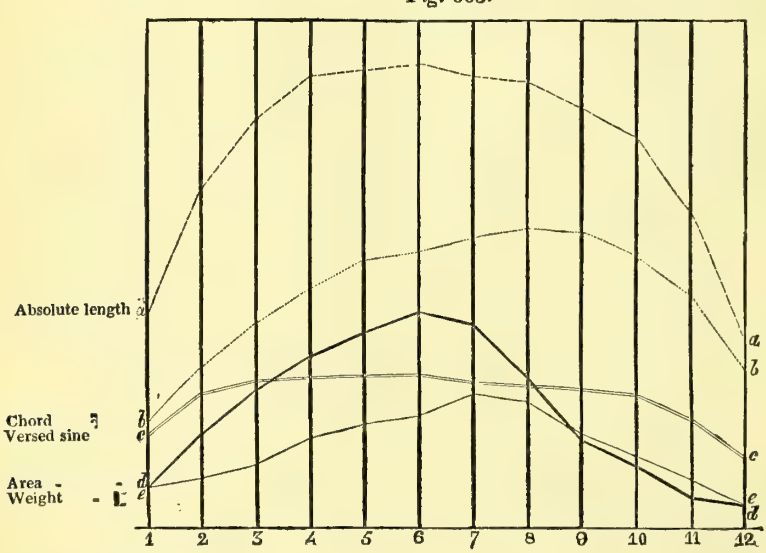
(a) *Absolute length.*—In the length from the anterior to the posterior extremity, (A C B, *fig.* 664.) the 12th rib is the shortest. The 11th rib is nearly double the length of the 12th rib; likewise the 2nd rib is nearly double the length of the 1st rib; therefore the 1st and 2nd, and the 11th and 12th differ more remarkably in their length than do any of the other ribs. The length (curve *a*, *fig.* 665.) suddenly increases up to the 4th rib; and then the difference is trifling to the 8th rib; after this the shortening is as rapid as in the four superior ribs.

(b) *Chord length.* — The dotted line *b*, *fig.* 665, represents this measurement. This length from tip to tip (A B, *fig.* 664.) of the rib is the chief modifier of the different apparent mobility of particular ribs. If we allow the range of *costal* movement to be the same in each rib, while each succeeding rib increases in its chord length, the *apparent* mobility in different ribs will increase exactly as their chord measurement increases. If a rib be three inches long, and if its free extremity by a given movement passes through one inch of space, the free extremity of a rib six inches long will, with the same absolute movement, pass through two inches. The chord length is an important element in modifying thoracic capacity. It is in this measurement that the 1st rib is the shortest and nearly one half the length of the 2nd rib, — as 2· is to 3·75. (Table A.)

The chord length (line *b*, *fig.* 665, compare with line *a*,) increases and decreases less abruptly than that of the absolute length.

If we were to admit that all the ribs at their fulcra possessed the same extent of motion, still the antero-posterior length of the thorax would be unequally increased, and that exactly in relation to the chord measurement;

Fig. 665.



and hence the 7th, 8th, 9th, and 10th ribs would advance most. It is a fact that in deep inspiration the lower part of the sternum advances most, somewhat representing the curve line *b*, *fig.* 665.

(c) *Versed Sine Length* (D C, *fig.* 664.) —

As the chord length is to the antero-posterior movement, so is this measurement to the lateral movement of the thorax. This is the most uniform measurement in the ribs. If the 1st rib be 1·75, the 2nd rib is to that as 3; and from this rib to the 9th rib, the versed sine never exceeds 3·5; hence the curve *c*, *fig*. 665. is more horizontal than any of the other curves. So likewise it will be found that the *lateral* enlargement of the thorax in deep breathing is more uniform than the antero-posterior enlargement. (See dotted line, *figs*. 711, 712. compared with dotted line, *figs*. 713, 714.) The space gained by the ribs rotating must be strictly in relation to the length between the deepest part of the arch and the chord line. (D C, *fig*. 664.) This measurement is greatest relatively in the 2nd rib, and absolutely smallest in the 12th rib, the curve here being very small.

The versed sine of the ribs corresponds with the great curve: if a rib were not curved at all, there would be no versed sine. The versed sine does not increase after the 4th rib; and the curvature of the first four ribs forms smaller circles than the rest. The 5th and 6th ribs, although rapidly increasing in absolute length (see Table A.), yet present nearly the same versed sine; and while the chord line increases up to the 9th rib, from the 6th to the 9th the versed sine decreases, showing that the circle or arch of the rib becomes larger as we descend, until the 12th rib, which describes the greatest curve and the shortest versed sine.

In fact there is little difference in the versed sine length from the 3rd to the 10th rib, as described by the double line *c*, *fig*. 665. This difference of arching of the ribs constitutes the conical form of the thorax, the smaller circles being at the apex, and the larger at the base of the cavity.

(2) *Weight*. — The ribs increase not only in their various measurements but also in their weight up to the 7th or 8th where they attain their maximum development. The faint continuous curve, *e*, *fig*. 665. is the line of the relative weight.

(3) *Torsion of the ribs* (*special characters*). —We have already mentioned that the ribs have two torsions, an anterior and a posrerior. No rib is entirely free from this twist. It is incorrect to believe that the 1st rib is without any torsion, and therefore that the whole rib in its length can touch the same plane. In fact the 1st rib may in one sense be looked upon as the most twisted of all the set, inasmuch as the flat sides which are internal and external in other ribs are in this rib inferior and superior.

Like other features, the degree of torsion in the different ribs is progressive towards a maximum, and then towards a minimum. The 2nd, 11th, and 12th ribs are most devoid of torsion. In the last two ribs the torsion appears less than it really is, because of their shortness and the large circle which they describe.

The two torsions in each rib are always in contrary directions, except in the 2nd rib, where they are both downwards, but the torsion is here very slight. In the 1st rib, as in the ten inferior ribs, they are in contrary directions to each other, so that its two ends cannot touch the same plane at the same time; but its anterior and posterior torsions are respectively contrary to those of the ten inferior ribs; its posterior torsion being, like that of the second rib, downwards, and its anterior upwards.

The relative torsion of the ribs may be expressed by giving the respective elevations of each extremity from the plane upon which they rest. Thus the posterior torsion is seen when the rib rests upon its *inferior* edge, and the anterior torsion when it rests upon its *superior* edge. In this way the following table is calculated.

Table B. — Torsions of the Ribs.

Ribs.	Posterior End Torsion Upwards.	Anterior End Torsion Downwards.
1	6·0*	5·0†
2	2·5*	3·0
3	3·0	3·0
4	12·5	4·25
5	13·0	12·0
6	12·25	21·5
7	18·00	29·5
8	21·25	28·0
9	21·25	25·0
10	9·50	17·5
11	1·50	5·5
12	2·00	4·5

If the posterior twist of the ribs upwards be expressed conjointly as 114, the anterior torsion downwards is 153; therefore the anterior torsion is greater than the posterior. The torsions in the 2nd, 3rd, 11th, and 12th are the least; and they are the greatest in the 7th, 8th, and 9th ribs. Moreover as the torsion increases at one extremity of the rib, for the most part it increases at the other likewise.

The ribs of some persons are much less twisted than those of others. This is particularly the case in young subjects before the age of puberty. In infants the torsions are imperceptible; therefore they increase as we advance to maturity. These torsions afford more favourable traction for the muscles. Where the respiratory movement is most apparent, as from the 4th to the 9th rib, the torsion is highest.

The posterior torsion gives the ribs, when placed in their natural position, a very oblique direction with reference to the spine. This is very important to remember; for the more oblique, the more favourable are they for mobility or for increasing the thoracic cavity. For the same reason the anterior torsion, being in a contrary direction to the posterior, increases still more the obliquity of the rib with refer-

* Downwards. † Upwards.

ence to the spine. But the relation of these torsions to the spine are different: the posterior torsion is relative to the spine laterally, while the anterior torsion relates to the spine more in the antero-posterior direction: they both conspire to increase the obliquity of the rib in *one* given direction,—from above downwards.

The torsion of the 1st rib, we have noticed, is directed in a contrary direction to that of other ribs; and we have observed that the presence of torsion in general favours muscular traction: but the 1st rib is an exception to this; here the torsion exists only between its two chief articulating processes, — the head and the tubercle: in the other ribs the torsion is between the tubercle and the body of the bone. The posterior torsion of the 1st rib appears to be merely destined to afford the head a more complete attachment to the body of the one vertebra (the 1st dorsal) to which that rib is fixed. A posterior torsion, in this short rib, is not needed for muscular traction, because here the scaleni are placed in the most favourable position — nearly at an angle of 90° with reference to the body of the bone in question, while their other insertion into the cervical vertebræ facilitates the most extensive and favourable means for its mobility, independently of any favouring twist in the rib for that purpose.

(4) *Surfaces* (*special differences*). — The thorax being conical, or somewhat barrel-shaped, it follows that the surfaces of the ribs, like the hoops of a very spherical barrel, must gradually change their direction; thus the surfaces of the 1st rib are nearly *superior* and *inferior*, this bone forming the lid to the thorax, while the surfaces of the 6th or 7th rib are *external* and *internal*, and as we proceed downwards to the 10th, 11th, and 12th ribs, the surfaces are again slightly tending towards a *superior* and *inferior* position, so that the internal surfaces of the 1st and 12th ribs are directed somewhat towards each other. The body of the rib, or that part which covers the lung laterally, and the anterior and posterior extremities, have also their surfaces inclined in different directions. Thus, take a perfect rib, say the 7th, laterally to the thorax the two surfaces are internal and external, while at the anterior end they are directed — external surface, forwards and downwards; internal surface, upwards and backwards; — at the posterior end, — external surface, upwards and backwards; internal surface, downwards and forwards. This is produced by their respective torsions. In some of the lower animals the ribs overlap each other like the tiles of a house; this sometimes threatens in man, particularly in diseases of the spine (*fig.* 666.), when they closely approach each other.

(5) *Specific differences of the extremities of the ribs*. — The greatest difference is in the posterior end of the rib. The anterior presenting little difference.

(a) *Anterior extremity*. — These are all hollowed out for their cartilage. As the ribs become more perfectly developed, for instance, the 5th, 6th, 7th, and 8th, the anterior extremity is broader, but not more deeply hollowed out than some of the other ribs, which are less perfectly developed, as in the 2nd and 3rd, or 11th ribs. This extremity is most pointed in the 12th rib.

Fig. 666.

Relation of the ribs to the spine in angular curvature.

(b) *Posterior extremity*. — The posterior extremity of the rib is more complicated, and has certain named parts, as the head, neck, tubercle, and angle, all of which become modified as we pass from above downwards. Their differences may briefly be noticed.

1*st Of the head*. — On the head of the rib, articulating with the vertebræ, a surface or facet is formed. The 1st, the 11th, and the 12th ribs articulate each with the body of one vertebra, and therefore they have *one* articulating surface. All the rest articulate each with the bodies of two vertebræ, and they consequently have *two* such articulating surfaces as already described. The head of the 1st rib is relatively larger than that of the others. For the most part, as the ribs increase in size, the head likewise increases, so that in the best developed rib the head and its surfaces are most perfectly formed, degenerating again to the 12th rib.

2*nd Of the neck*. — The neck being that part of the rib between the articulation of the rib with the bodies of the vertebra, and that with the transverse process, and these points differing but little in their distance from each other in the dorsal vertebræ, it follows that the absolute length of the neck of the different ribs is nearly the same. The necks of the ribs differ in their thickness, accordingly as their respective ribs increase or diminish in size; therefore, in the middle set of ribs, the necks are the thickest and strongest. In the 11th and 12th ribs, the neck, according to our definition, does not exist.

3rd Of the tubercle. — As the tubercle articulates with transverse processes, those ribs which have no such articulation have no tubercle; this is the case in the 11th and 12th ribs. The tubercles are most prominent in the superior ribs, gradually degenerating, or becoming less apparent, down to the 10th, where it is almost rudimentary.

4th Of the angle. — In strict anatomical language, the 1st rib has no angle, but the tubercle is very prominent, and gives the bone a very angular appearance, likewise in the 2nd, 3rd, 11th, and 12th ribs the angle is almost imperceptible, whereas it is well marked in the 4th, 5th, 6th, 7th, 8th and 9th ribs.

(6) *Groove* (*specific differences*). — The groove is not perceptible in the 1st, 11th, and 12th ribs, but distinct in all the intervening ones.

The 1st rib has two depressions separated by a tuberosity. The anterior corresponds to the subclavian vein, and the posterior to the artery of the same name.

Costal cartilages. — The flexibility and elasticity of the ribs is partly owing to their structure, but more especially to the cartilages which prolong them in front. (*figs.* 661, 662.) There are twelve costal cartilages distinguished numerically, as 1st, 2nd, 3rd, &c.; they are separated from each other by intervals which are very considerable at the upper part of the thorax, but gradually diminish as we proceed downwards. It is not very uncommon to meet with thirteen cartilages on one side, and at other times there are only eleven. Sometimes two cartilages are joined, and so aticulate with the sides of the sternum; when there are thirteen cartilages, the supernumerary one generally exists between the 3rd and 4th ribs; it is thin, and as it were rudimentary; it does not form the continuation of any rib, and terminates insensibly in the muscles. The cartilages from the 1st to the 7th articulate immediately with the sternum; and hence the name of sternal given to ribs with which they are connected. Of the other five cartilages, the last two have no connection with that preceding them; and from this circumstance, the name *floating* has been given to the last two ribs.

General characters of the costal cartilages. — All the costal cartilages are flattened like the ribs, and precisely resemble in breadth and thickness the bones to which they are attached. The external end is received into a cavity hollowed out in the anterior extremity of the rib; their internal or sternal extremity, which is much narrower than the external, is angular and articulates with the corresponding angular surfaces of the sternum. (*fig.* 661.) Their anterior or cutaneous surfaces are slightly convex, and covered by the muscles of the anterior region of the trunk, to many of which they give attachment. Their posterior or mediastinal surfaces are slightly concave. Their superior and inferior edges bound the intercostal spaces, and give attachment to the intercostal muscles. "They are," says Cruveilhier, "altogether distinct from articular cartilages, and have a peculiar tendency to ossify, this process taking place partly on the surface, and partly from within outwards."

Differential characters of the costal cartilages. — The costal cartilages, like the ribs, increase in length, from the 1st to the 7th, and sometimes the 8th, which in this case articulates with the sternum; from this they diminish in length to the 12th rib When we recollect the conical shape of the thorax this difference is to be accounted for, and moreover, the osseous parts of the upper ribs terminate anteriorly in a line directed obliquely from above downwards and outwards. The sternum is only about half the length of the lateral pectoral space, so that only the first four or five cartilages could join this bone, did not the others turn upwards to reach its sides (*fig.* 661.), by joining the lower edge of the immediately superior cartilage. The first three cartilages alone, therefore, follow the same direction as the long rib to which they articulate.

The *first cartilage* differs from all the others by its shortness, its thickness, and breadth, and its tendency to ossify; it is often, but not always, continuous with the sternum.

The 2nd and 3rd costal cartilages cannot be distinguished from each other, but they differ from the rest in being joined to the sternum at right angles, in not being bent, and in being as broad at their sternal as at their costal extremities.

The 4th cartilage becomes bent upwards, after having followed the direction of the rib for a little way. (*fig.* 661. *e.*) The length and the curvature of the cartilages of the 5th, 6th, and 7th ribs progressively increase, and across their intercartilaginous spaces they frequently touch each other. Their inner ends become successively narrowed so as to correspond with the diminishing cavities on the edges of the sternum. The borders of the 5th, 6th, 7th, and 8th costal cartilages articulate together, and present for this purpose articular facets supported by eminences. The cartilages of the 8th, 9th, and 10th ribs gradually diminish in length. Externally they have the same breadth as the rib, and decrease as they pass inwards, so as to terminate by a pointed extremity, which is applied to the lower edge of the cartilage above. The cartilages of the 11th and 12th ribs are extremely short, particularly that of the 12th, which is only a mere tip to the bone, and seldom exceeds four or five lines in length; their free extremity loses itself, so to speak, in the substance of the abdominal parietes; so that they are altogether unconnected with the other cartilages.

Liability of the costal cartilages to ossify. — The 1st cartilage usually becomes more or less ossified in adult age, and is often anchylosed to the sternum. After the middle period of life, osseous matter is likewise deposited to a greater or less extent in the other cartilages, and it is apparent in those of the false, later than in those of the true ribs.

These observations apply to the male body; for in the female the process of ossification does not affect the cartilages until old age has arrived, and it always affects a comparatively small number of cartilages, even if it should happen to extend beyond the 1st, which commonly is not the case.

Of the ligaments of the ribs. — The ligaments of the ribs may be divided into three sets, those which connect them, 1st, with the bodies of the vertebræ; 2ndly, with the transverse processes, and 3rdly, with the sternum. The rib is connected with the bodies of two vertebræ (excepting those specified above) forming with each a joint lined with synovial membrane, and held in place by the following ligaments: —

1st. With the bodies of the vertebræ. — *Costo-vertebral ligaments, (lig. capitulorum costarum).* — These consist, 1st, of an anterior ligament which connects the head of each rib with the sides of the bodies of the vertebræ. Its fibres, flat and radiated, are divided into three bundles, of which the middle one passes horizontally forwards upon the corresponding inter-vertebral cartilage, whilst the superior ascends to the body of the vertebra above it, and the inferior descends to that below. From the divergence of its fibres this is usually called the *stellate ligament.* 2ndly, of an *inter-articular ligament*, a thin and short band of fibres which passes transversely from the ridge separating the two articular surfaces on the head of the rib, to the inter-vertebral substance, and divides the articulation into two parts, each lined by a separate synovial membrane. This ligament does not exist in the articulation of the 1st, 11th, and 12th ribs, and in consequence there is in them but one synovial membrane.

2ndly. With the transverse processes of two vertebræ. — The rib at its tubercle forms a joint, lined by synovial membrane, with one transverse process; and to another (being separated from it by a considerable interval), it is connected by ligamentous structure of some length. The *costo-transverse ligaments* connect the tubercle and neck of the rib with the transverse processes of the vertebræ; they are named from their position, posterior, middle, and anterior.

a. The *posterior costo-transverse ligament* — (*lig. transversum externum costarum*, Weitbr.) consists of a very short, thick fasciculus of fibres, which passes from the posterior surface of the summit of the transverse process, to the rough, inarticular part of the tubercle of the rib. Those of the superior rib ascend, those of the inferior rib somewhat descend.

b. The *middle*, or *interosseous costo-transverse ligament* — consists of a series of very *short* parallel fibres, which unite the neck of the rib to the anterio surface of the contiguous transverse process. These fibres are best seen by removing horizontally a portion of the rib and transverse process, and forcibly drawing one from the other.

c. The *anterior*, or *long costo-transverse ligament* — (*lig. transversum internum seu cervicis costæ internum*, Weitbr.), is usually divided into two fasciculi of fibres nearly opposite to one another, and on the same plane. They pass from the neck of the rib obliquely upwards and outwards to the lower, margin of the transverse process next above it.

Characters peculiar to certain costo-vertebral articulations. — The articulations of the 1st, 11th, and 12th ribs alone present peculiarities.

a. Costo-vertebral articulation of the 1st rib. — The rounded head of the 1st rib is received into a cavity on the side of the body of the 1st dorsal vertebra, the articulation is therefore a species of enarthrosis; there is neither a costo-vertebral interosseous ligament, nor a superior costo-transverse ligament; the synovial membrane is much looser than in the corresponding articulations of other ribs.

b. Costo-vertebral articulation of the 11th and 12th ribs. — These present the same characters as the preceding, in this respect, that the anterior cavity for the head of the bone is situated upon a single vertebra. The head of the rib, however, is flattened, or very slightly convex. There is no interosseous costo-vertebral ligament. The superior costo-transverse ligament is much broader and stronger than in the other articulations. As the 11th and 12th ribs have no tubercles, and the transverse processes of the corresponding vertebræ are but little developed, it follows that there is no costo-transverse articulation: but yet there is a costo-transverse interosseous ligament. All these ligaments are much more loose than in the other articulations.

3rdly. With the sternum (*Chondro-sternal articulation*). — The costo-sternal articulation is between the angular extremities of the cartilages of the ribs and the corresponding fossæ in the margins of the sternum; these articulations are covered and supported by two sets of ligaments. 1st, by an anterior set of ligamentous fibres, thin, scattered, and radiated (*ligamenta radiatim disjecta* Weitbr.), passing from the extremity of the cartilage to the anterior surface of the sternum, where they interlace with those of the opposite side, and are blended with the aponeurosis of the pectoralis major muscle. 2ndly, by a posterior set of fibres similarly disposed, but not so thick or numerous, connecting the thoracic surfaces of the same parts; together with some ligamentous fibres placed above, and others below the joint.

A synovial membrane is interposed between the ends of each true rib, and the sternum. These membranes can be demonstrated by slicing off a little of the anterior surface of the sternum and cartilages. Cruveilhier doubts the existence of such synovial membranes; we are inclined to differ from him in this respect.

Characters peculiar to chondro- or costo-sternal articulations. — The 1st, 2nd, 6th, and 7th chondro-sternal articulations present the following peculiarities: —

1st, The cartilage of the 1st rib is sometimes continuous with the sternum, and is sometimes articulated like the cartilages of the other ribs. Cruveilhier found in one subject the 1st rib excessively moveable, because its cartilage, instead of being continuous with the sternum, had its upper edge applied to the side of that bone to which it was united by ligaments, and was ultimately articulated by a narrow extremity immediately above the 2nd rib.

2ndly. The second cartilage is much more angular at its inner extremity than any of the others : it is received into the retreating angle formed by the union of the first two pieces of the sternum. Sometimes there is an interosseous ligament in this joint, running from the angle of the cartilage to the bottom of the cavity, and there are then two synovial capsules; in other cases there is only one, but it is always more marked than in the other joints.

The articulations of the 6th and 7th cartilages, besides the anterior ligaments, have also a *chondro- or costo-xiphoid ligament*, more or less strong, which crosses with the ligament of the opposite side in front of the ensiform cartilage, and the lower end of the sternum. Sometimes this ligament only exists for the 7th cartilage ; it is intended not only to strengthen the chondro-sternal articulation, but also to maintain the xiphoid appendix in its place.

Connection of the ribs with their cartilages. — The cartilages are almost immoveably united to the ribs, being received into rounded depressions on the ends of the ribs, and their union is maintained only by periosteum, which may be considered to represent their ligaments.

Articulations of the costal cartilages one with the other. — Some of the costal cartilages articulate with each other by their edges.

The 1st, 2nd, 3rd, 4th, and 5th costal cartilages do not articulate together, unless the aponeurotic lamellæ, sometimes very strong, which form the continuation of the external intercostal muscles, and occupy the whole length of the cartilages, be considered as uniting media.

The 6th, 7th, and 8th cartilages, frequently the 5th, and sometimes the 9th, present true articulations with one another. Cartilaginous processes arise from the neighbouring edges and come in contact with each other : there are sometimes two articular faces between the 6th and 7th cartilages. The means of union are some vertical fibres united in bundles, so as to form two ligaments, the one anterior and thicker, the other posterior and thinner. The edges of the articulating surfaces, from the 6th to the 8th or 9th, are lined by synovial membrane. The 7th, 8th, and 10th cartilages have not always articular surfaces, but are simply united by vertical ligaments.

Ligaments of the sternum (*Membranæ sterni*, Weitbr.). — The pieces of the sternum are connected by a layer of fibro-cartilage, placed between their contiguous borders ; and, on the anterior and posterior surfaces, ligamentous fibres may be observed running longitudinally, which serve to strengthen their connection. They are sometimes called the anterior and posterior sternal ligaments. The longitudinal fibres are mixed with those radiating from the costal cartilages, especially in front of the sternum, where likewise they blend with the aponeurosis of the pectoral muscles. The anterior portion has thus most of the accessory fibres, and is rough and irregular ; the posterior one is smooth and pearly in its aspect.

The *muscles* of the thorax will be more conveniently noticed hereafter.

Of the Thorax in general. — The sternum, the ribs and their cartilages, together with the dorsal vertebræ, are so united together as to compose the frame-work of the thorax. (*fig.* 662.) Their arrangement is such as collectively to admit of great mobility, and at the same time to protect completely the organs of respiration and the heart. How well adapted this mechanism is for protecting those vital organs is well shown by the impunity with which the prize-fighter receives for many hours the trained blows of his antagonist.

Although the range of motion between each vertebra and the ribs attached to it, is very limited, yet the whole frame-work of the chest enjoys such mobility, that, by a deep inspiration, its capacity is sometimes more than doubled. This bony frame-work is by no means destined solely to cover the respiratory organs, for it extends considerably downwards, composing part of the abdominal walls within which lie the liver, spleen, kidneys, stomach, duodenum, and part of the colon ; hence the distinction between thoracic and diaphragmatic ribs. In fact it will be found that about one half only of the costal surface is destined to compose the thorax. The shade running transversely across the ribs in *fig.* 632. marks the bottom of the thoracic cavity.

In each individual the thoracic cavity corresponds exactly with the volume of the heart and lungs. But there is no relation between the volume of the lungs and the vigour of the constitution — nor between the size of the cavity of the thorax and the amount of air which can be respired, as will be hereafter shown. There is likewise no relation between the volume of the thorax and that of the abdominal cavity. No doubt the vigour of aëration in the lungs is at all times exactly commensurate with the vigour of the alimentary canal, so that the one harmonises with the other; but this *vigour* bears no relation to space or *size*. A small thorax may in some individuals admit of the inspiration of a greater volume of air than a larger thorax in others. In fact it may be commonly noticed that where there is a large abdomen there is generally a small thorax, and that the volume of air which can be expelled at one effort from the lungs of those who have a large abdomen, is less than from those with a small abdomen. The alimentary canal receives at once a given quantity of food, and there it remains for an indefinite time, the thorax large or small, it matters not which, aërates the blood from this food by movements, quick or slow, long or short; therefore the respiratory *movements* only, need be relative to the abdominal cavity, in the same way as the volume of the blast from a pair of bellows is more dependent on their mobility than on their absolute size. The above remarks are applicable to the thorax of either male or female.

I. *Boundaries of the thoracic cavity.*— The thoracic cavity, situated between the shoulders and below the neck, extends but a short way downwards, in the male about seven inches, and in the female about eight inches, below the clavicle, so that a horizontal line drawn about an inch below the axilla, corresponds (roughly) with its floor. The floor of the chest, therefore, is much higher up in the trunk of the body than is commonly supposed. The thorax is bounded anteriorly by the sternum and costal cartilages; laterally by the bodies of the ribs and the intercostal muscles; posteriorly by the vertebræ and angles of the ribs, and inferiorly by a thin tendinous and fleshy floor— the diaphragm. The *surior aperture* of the chest is about sixteen inches in circumference, this is the smaller end, and thence called the apex of the thorax. It is bounded *laterally* by the two 1st ribs, *anteriorly* by the upper edge of the sternum and inter-articular ligament, and *posteriorly* by the last cervical and first dorsal vertebræ. The *inferior aperture* is about thirty or thirty-one inches in circumference, and forms the base of the chest. Anatomists describe this part as bounded in front by the cartilaginous extremity of the sternum or xiphoid cartilage, and the cartilaginous extremities of the last true and false ribs, and more laterally by the 11th and 12th ribs, posteriorly by the last dorsal and first lumbar vertebræ. But as they assume to themselves the privilege of giving a bone a surgical neck as well as an anatomical one, so may we take a similar liberty in describing the thorax for medical purposes. In the examination of the chest during life, too exclusive attention to anatomical boundary has probably led to the error, of regarding the chest as much deeper than it really is, and thence to examining for disease of the lung where really little or no lung exists. A sharp instrument, piercing the chest laterally, at the cartilaginous extremities of the last true ribs, would most probably penetrate *no lung*, for the liver, spleen, stomach, &c. are contained within these points. The bottom of the chest is so moveable and so much arched (*See art.* DIAPHRAGM, *fig.* 3.), that in the different stages of inspiration, the lung assumes different positions This may be demonstrated by percussing over the 5th rib at its junction with its cartilage, first after a deep expiration and then after a deep inspiration; in the latter the sound is "clear," in the former it is strikingly "dull." Therefore, instead of taking the insertion of the diaphragm as the bottom of the thorax, it will be found more convenient for examining the chest to take the top of the arch of this muscle as the lower thoracic boundary, or the shaded line crossing the ribs in *fig.* 4., for the *medical base.* This may be described as corresponding in front with the xiphoid cartilage; laterally to different *osseous portions* of the 7th, 8th, 9th, 10th, 11th, and sometimes the 12th rib (*fig.* 682.), and posteriorly to the 8th and 9th dorsal vertebræ. This will place the bottom of the thorax in a very different position from what is generally supposed; for, if we express the distance from the 1st rib, to the lowest point of the 10th rib as 13·5, that from the 1st rib to the arch of the diaphragm or medical boundary will be only 6·25, less than one half the depth of the thorax as anatomically described. The medical base of the thorax forms a nearly horizontal plane, which extends between the sternum and the bodies of the 9th or 10th dorsal vertebræ, its posterior being somewhat higher than its anterior. But on each side of the bodies of the vertebræ there is a deep groove formed by the angles of the ribs. In that part of this groove which extends below the above-mentioned inclined plane, a wedge-shaped process of lung is lodged, which varies in size in different subjects, and consequently will be found to terminate at different points in the dorsal region, as already noticed, sometimes hanging down like a broad, thick flap, and at other times forming only an insignificant process.

In examining the chest, it is of paramount importance that the student should familiarly know this *medical floor* of the thorax. The sign laid down by the late Dr. Edwyn Harrison, for marking this boundary, we have found strictly correct in every normal-shaped thorax. Namely, take the xiphoid cartilage as a point to start from, and pass the *flat* hand horizontally from thence to the side of the chest, the index finger, when *horizontal,* will distinguish a slight depression or sulcus at the maximum lateral bulge of the thorax, then from this point slide the hand slightly upwards (perpendicularly), and it will pass over a bulge, about enough to fill the palm of the hand, into another sulcus, better defined than the former one; this groove corresponds with the medical base of the thorax, and a probe passed in here would graze the arch of the diaphragm after passing through the moveable inferior edges of the lungs. It is necessary that the hand be kept perfectly horizontal, or it will fall into an intercostal space, which does not correspond with the groove in question. With practice, the hand falls at once into the upper sulcus, without first searching for the lower one; indeed, latterly, Dr. Harrison allowed that the lower sulcus might be absent, and yet the upper one present.

This groove is higher upon the right side than upon the left, corresponding to the height of the liver.

By external observation, the medical base of the thorax may be known by the slight rotatory motion made upon the diaphragm when a person is walking. A kind of great ball and socket-joint may be conceived to exist between the abdomen and thorax, and the outer garments even exhibit a correspondence to this base of the thorax.

II. *Contents of the thorax.* — Not only does the thorax contain organs proper to itself, but it lodges and protects others passing to the abdomen; thus, the food we eat passes through the thorax to enter the stomach, while the eighth nerve both supplies the lungs and then passes onwards to the stomach. Like other cavities, the thorax is lined with a serous membrane (*pleura costalis*), which likewise invests the lungs (*pleura pulmonalis*) (See PLEURA). The heart and its blood-vessels, the trachea, and the lungs, almost completely fill the thorax. The remaining organs, viz., the origin of the sterno-hyoid and -thyroid muscles, remains of the thymus gland, lymphatic glands, mammary vessels, triangulares sterni muscles, the phrenic, the eighth pair, and the splanchnic nerves, the œsophagus, thoracic duct, vena azygos, and venæ cavæ, occupy very little space.

Thus the thorax is completely filled. The older anatomists, however, even as late as Benj. Hoadley's time, considered that there was a considerable space containing air, between the lungs and the walls of the thorax. Now, we know that any considerable accumulation of air in this situation would be destructive to the respiratory function.

III. *Shape of the thorax.*—The shape of the thorax is subject to many varieties which may be conveniently studied under the following headings:

External thorax. — The thorax in the perfect subject is somewhat conical, broader above than it is below; but when deprived of the upper extremities and their appendages, the contrary obtains, for it is narrower above than it is below (see *figs.* 662. and 630. *et seq.*). Therefore the notion we commonly connect with broad shoulders or broad back, has but a feeble relation with the absolute breadth of the thorax. In fact the diameter of the neck corresponds more correctly with the diameter of the upper part or true apex of the thorax. Freeman the American giant measured 26 inches from tip to tip of his shoulders, while the diameter at the lower part of his neck, in the same direction, was only 6 inches. In women the mammæ materially add to the dimensions of the chest towards the apex. We have found the measure of a female round the thorax over the mammæ 45¼ inches, while the root of the neck was 15 inches. Allowing two inches for muscle, &c., the true thoracic apex would not exceed 13 inches, whilst 45¼ inches was the apparent circumference of the thorax. The true apex of the thorax is loaded with large muscles, sometimes a vast quantity of fat, the upper extremities, and in the female with large mammæ besides. The true base of the chest is comparatively little covered, particularly below the axilla, where the serrati are seen. This is the weakest and thinnest part of the thorax, but it is well protected by the arms.

(a) *The anterior or sternal region of the thorax.*—In a well-developed thorax the sternum appears to lie in a fossa formed by the pectorales and mammæ. This region assumes more or less of the perpendicular, according to the carriage of the person; a perpendicular drawn to the external plane of the sternum would, however, be directed upwards. Laterally to this, the costal cartilages articulate with the sternum; and, still more laterally, the ribs and their cartilages unite, forming an oblique ridge from above downwards. (See *figs.* 680. and 681. the line on each side of the sternum.) Still more externally, and parallel to this, may be noticed the projections formed by the anterior angles of the ribs, which bound the anterior region.

(b) *The posterior or vertebral region.* — In the well-developed thorax the spines of the dorsal vertebræ lie in a deep groove formed by the great mass of the erector spinæ on either side. These masses extend outwards to about the posterior angles of the ribs, which are nearly in a plane with the spinous processes of the vertebræ, and may be easily distinguished, bounding the posterior region.

(c) *The lateral or costal region* is composed of the bodies of the ribs and the intercostal spaces. Much difference has prevailed amongst writers upon various points connected with the ribs, and the spaces between the ribs. Probably this may have arisen from their having made their observations upon the dead subject, wherein the ribs have collapsed to their minimum, or the thorax of a thin subject with the ribs expanded by, perhaps, 200 cubic inches of air, or the ribs when artificially articulated in the clean skeleton, wherein they are generally arranged too wide apart and too horizontal.

In the collapsed state of the ribs, *i. e.* after the most ample expiration by death, we notice

1st, That the intercostal spaces are *not* of a uniform width from the vertebræ to the sternum. They are most narrow behind, and become wider as they approach the sternum (*fig.* 680.). The 1st, 2d, and 3rd spaces upon the whole are broader than the five next inferior, and the 10th and 11th spaces are the widest (*fig.* 682.).

2dly, Their length differs with the length of the ribs; thus the two first and two last spaces are the shortest.

3dly, The position of the intercostal spaces is very oblique (*fig.* 684.), roughly speaking, about mid-way between the horizontal and the perpendicular.

4thly, They are moveable, and in the different stages of respiration they can assume different positions and different perpendicular widths.

It has been found necessary for the convenience of auscultation, to subdivide the thorax more minutely. The subdivision proposed by Laennec has been generally adopted, although some of the terms, like those of the respiratory sounds, have been modified by writers of later date.

The anterior and lateral superior division,

Table C. — Thoracic Regions.

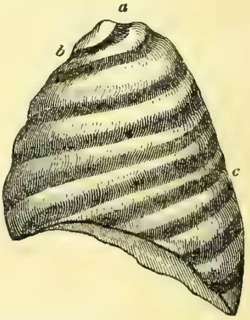
REGION.	SITUATION.
Anterior:	
Clavicular (subclavian of Laennec) - -	Portion covered by the clavicle.
Infra-clavian (anterior superior of Laennec)	Between the clavicle and 4th rib inclusive.
Mammary - - - - - -	Between the 4th and 8th ribs.
Infra-mammary (sub-mammary of Laennec)	From the 8th rib to the cartilaginous border of false ribs.
Sternal — superior, middle, inferior - -	Over the respective parts of the sternum.
Lateral:	
Axillary - - - - - -	All the axilla to the 4th rib inclusive.
Infra-axillary (lateral of Laennec) - -	Between the 4th and 8th ribs at the side.
Inferior-lateral - - - - -	Below the 8th to the false ribs inclusive.
Acromial - - - - - -	Between the clavicle, neck of humerus, and along the upper margin of scapula, including the root of the neck.
Posterior:	
Scapular, upper and lower - - -	Supra-spinous fossa and infra-spinous fossa.
Interscapular - - - - - -	Between the inner margin of scapulæ.
Infra-scapular (inferior dorsal of Laennec)	Below inferior angle of scapula and border of serrati to the level of 12th vertebra.

give the clearest sound upon percussion, and the back the least clear. Below Harrison's line, there is little or no evidence, from percussion, of the presence of lung, except in deep inspiration, and then the sound on percussion is mixed with other sounds from the abdominal organs. Only a small part of the mammary region covers lung, scarcely any being subjacent to the anterior parts of the 6th, 7th, and 8th ribs. (See *fig.* 4, wherein a transverse shading indicates the diaphragm.)

Internal conformation of the thorax. — To comprehend clearly the internal shape of the thorax, it is necessary to take a cast of this cavity. This may be done by making an opening in the sternal region, just large enough to admit the hand to remove the heart and lungs, filling up the whole of the cavity with plaster of Paris and returning the sternum, then opening the abdomen, cutting away the diaphragm, and so removing the cast, which gives us a clear knowledge of the internal conformation, and every kind of measurement correctly. (*Fig.* 667. is a cast from the cavity of *figs.* 680—685, — male subject.) We have stated that the perfect thorax viewed externally, and the same when the superficial muscles and upper extremities are removed, differ widely in their relative form. The thoracic *cavity* likewise differs remarkably from either of these views. The general view is that of a cone, but broader from side to side than from before backwards: therefore the cone is somewhat flattened.

(a) *Anterior region.* — This very closely resembles the anterior region of the external surface, being *convex* in its form, precisely corresponding with the concave sternum. The upper part, immediately behind the superior end of the sternum, is rather concave (*fig.* 667). At this part the cavity divides into two small cones, for the reception of the right and left apices of the lungs, which ascend upwards to a variable height, — an inch or an inch and a half. Both apices of the lungs are directed from below, upwards

Fig. 667.



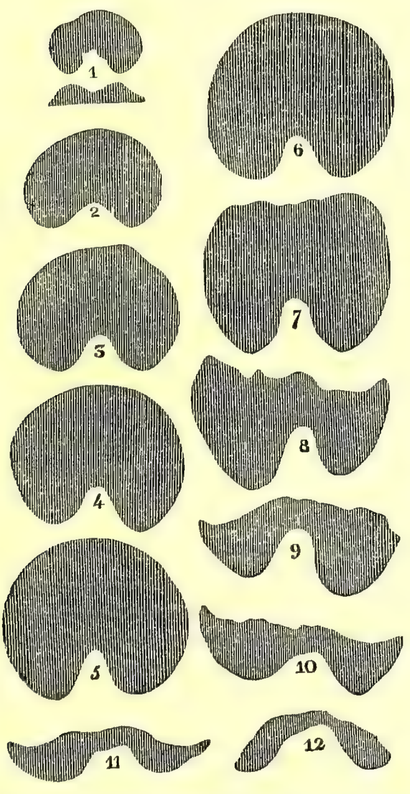
Cast of the cavity of the thorax represented in figs. 1, 2, 3, 4, 5, *and* 6.

and *forwards;* it is incorrect to consider them as directed backwards (*fig.* 667. *a*, which is the left apex seen above the 1st rib.) In some cases, particularly where the lung presents a puckered appearance, the axis of the apex is inclined nearly to the horizontal, and at all times it is about perpendicular to the sternum. These apices, throughout advancing life, are tending to incline forwards; it is this portion above the 1st rib (*fig.* 667.), which is so vulnerable in phthisis pulmonalis. There is great difference in the precise character of these apices in different individuals; in fact we have seen no two the same; some are remarkably truncated, and broad from before backwards; others are thin in this direction, and pointed; some obtuse and low, others acute and high. They have the same characters in both sexes. There is little difference in the height of the two apices. The elevation of the liver on the right side does not necessarily cause the right apex to be the higher. The right lung is more shallow than the left; but this is not because it is "pushed up," but because, in order to accommodate the liver, there is less *lung-substance* on the right side. If the mean of a series of observations represents the right side of the thoracic cavity as equal to 151, the left may be given as 182. The same may be said of both sexes.

(b) *Posterior region.* — If we examine this region upon a cast of the thoracic cavity, we observe in the middle line a deep fossa, formed by the projection, to the very centre of the thoracic cavity, of the bodies of the dorsal vertebræ.

This fossa is wider towards the base of the thorax, as may be seen by comparing the different sections of the cast (compare the notches, 10, 11, and 12, with those of 3, 4, and 5 in *fig.* 668.).

Fig. 668.



Sections of a cast of the thorax showing the space encompassed by each pair of ribs respectively.

The bodies of the thoracic vertebræ, form almost a complete septum; they are certainly a central column of support for the whole trunk of the body, bearing an equal distribution of the superincumbent weight in all directions. There is no part of the skeleton which more strikingly demonstrates that man was destined for the erect posture, than this central position, together with the increasing dimensions from above downwards, of the vertebral column. These conditions exist only in the human subject. The groove in the cast formed by the dorsal vertebræ is directed upwards and *forwards*, so that at the apex of the thoracic cavity it completely divides the lungs, producing two little cones laterally for the lungs, forming the right and left apex.

At the base of the thorax this perpendicular column again completely divides the lower lobes of the two lungs. The shape of the posterior part of the cast is that of a curve directed upwards, and sharply forwards, near the apex (*fig.* 667.). This curve near the apex is, like the form of the apices, very various.

An inflated lung assumes the same shape as this cast, giving even the marks of the ribs. The student, in order to have a correct idea of the lungs, should remove them from the body with the heart attached; then inflate them to their utmost, when their shape, their lobes, and relative mass before and behind, are clearly seen.

If now we inspect the cavity of the thorax itself, we find that the bodies of the vertebræ by their projection as above described, divide the posterior portion of the chest into two vast lateral grooves, which lodge the posterior portions of the lungs; these two grooves, partaking of the form of the thorax, are consequently conical in their configuration. They lodge fully one half of the entire lungs. This is worthy of remembering in reference to diagnosis, particularly when pneumonia is suspected; in such cases auscultation of the dorsal region demands as much attention as that of the anterior region. Though less vulnerable to phthisis pulmonalis, yet it may lodge disease in parts comparatively remote, and where inflammation may insidiously gain serious ground upon the patient, particularly in children.

(c) *Lateral region.* — This precisely corresponds with the external lateral view of the thorax (compare *fig.* 667. with *fig.* 680.); it presents indentation of the ribs, resembling a diagonal, curved, grate.

(d) *The base* of the thoracic cavity has been described above.

Conformation as affected by age and sex. — *Age* alters the conformation of the chest. In the earlier periods of existence the thorax is the smallest of the three great cavities, probably from the inactivity of the lungs. In the fœtal thorax the antero-posterior diameter exceeds the transverse diameter, the sternum projecting forwards, and the heart and thymus gland filling up the middle of the cavity. The ribs in fœtal life are less curved, and consequently those deep grooves, seen in the interior of the chest on each side the spine, formed by the angle of the ribs, so conspicuous in after life, are almost wanting; the vertical depth also is much less at this period, because the lungs are unexpanded and unemployed, while the abdominal viscera, particularly the large liver, are in activity and pushing up the diaphragm. The superior opening or true apex is greater from before backwards than transversely, which is the very contrary to the adult conformation. The inferior or true base of the thorax is extremely wide in every direction, from the encroachment of the abdominal viscera. At birth the thorax suddenly enlarges, by the air expanding the lungs to two or three times their previous cubic dimensions. As age increases, the curvatures of the ribs increase, and, with the vertebræ, running up through the very centre of the thorax, form the two great lateral grooves, peculiar to man, for lodging the chief bulk of the lungs. The depth of the thorax is diminished, while its breadth is increased, and this participates in that more perfect development of the system at the age of puberty. It is at this time that malformation of the chest frequently becomes obvious, particularly in females. In the adult age the thorax still grows, but in a degree less apparent, until it assumes the form of what is termed an open chest, capable of expanding in any direction, supplying us with air under violent exercise, and resisting severe blows. As age advances, through the decline of life, the thorax has a tendency to collapse ; the bony framework threatens to unite into one rigid cage, the true apex droops forward, the shoulders appear higher, and the round back of old age becomes apparent, so that we may make a tolerable guess at the age of an individual by the conformation of the back. The erect thorax is absolutely necessary to healthy vigour, while the drooping-forward chest is always accompanied with proportionate feebleness.

Sex. — The chief difference of external conformation between the sexes is due to the largeness of the mammæ, and the less width across the shoulders in women than in men. There is no distinguishing the sexes by the internal form of the thorax, they so perfectly resemble each other. The chest of the female is only absolutely smaller, but not always that, certainly not relatively so. The nipples are not uniformly in the same position ; those of the female are generally closer together than those of the male.

Conformation of the thorax affected by disease and occupation. — The conformation of the thorax chiefly depends upon the healthy condition of the main pillar of support, the spine ; but not always so, for that deformity called "chicken breast" appears to be independent of the condition of the spine. And, again, emphysema of the lungs tends to protrude the ribs and advance the sternum.

Disease, as caries of the vertebræ, or an atonic condition of the thoracic muscles, owing to which the spinal column may yield, either laterally, producing "lateral curvature," or anteriorly, giving "angular curvature," produces the most marked distortion of this pillar of support, and consequently of the whole thorax. In youth, particularly in females, (from the present system of education,) the spinal column, which is at all times sufficiently flexible, bends under the weight of the head and arms ; and for want of proper exercise the muscles of the back become enfeebled, and unable to restore it to the erect position. When "rickets" attack the spine, it may curve in any direction, compressing the ribs and projecting the sternum. It is surprising to witness to what an extent of deformity the thorax may attain, and yet life still remain (see *fig.* 666., where costal respiration could not exist ; and where all the abdominal viscera must have been forced up into the cavity of the thorax, for the 10th rib is nearly touching the crista of the ilium). We have noticed a case where such was the effort of nature to preserve the thoracic and spinal cavities, that life was maintained in a boy 14 years of age, though 7 bodies of dorsal vertebræ were completely absorbed.

In emphysema of the lungs, the sternum is protruded, and the antero-posterior diameter of the thorax is increased sometimes by an inch, the shoulders are raised, and the person assumes always the form of a man who has made the deepest inspiration.

In phthisis pulmonalis, the thorax changes its form, which is manifested by the shoulders inclining forwards, the anterior and superior parts bending in the same direction; the otherwise round full apex becomes flattened, collapsing upon itself; and there is an incapacity to extend the apex ; this is a sure and delicate test of that disease threatening, before any symptoms can be detected by auscultation. In other stages there is a loss of symmetry in the sides. In pleuritic effusion or in empyema, one side may be full and immovable, whilst the other has to perform the respiratory functions. In fact, disease of the respiratory organs may produce a change in the form of the thorax, either downwards, upwards, or outwards, or by collapse of the apex.

Frequently repeated or permanent compression, may produce many varieties of conformation of the thorax. Cruveilhier observes that infants, in whom the thorax was perfectly well formed at birth, have become deformed and flattened on the sides of the thorax, *by pressure from the hands of the nurse.* Slight external pressure in early life may be productive of permanent deformity of the thorax. The effect of strong and permanent constriction, as from tight stays, occasions a distortion in the form of the chest. This kind of compression principally affects the lower part of the thorax ; so that the 5th, 6th, 7th, 8th, 9th, and 10th ribs are pressed forwards and inwards, because the length of their cartilages allow them to yield readily : and the viscera corresponding to these ribs, also undergo alteration in their position and figure, encroaching upon the thoracic cavity, compressing the lungs upwards, into the apices of the chest. The imprudent custom of females wearing a hard unyielding piece of wood, steel, or whalebone up the front of their corset, commonly produces a compression inwards of the sternum. We once noticed a case where the sternum was forced inwards to such an extent, that the entire depth of the thorax, by *external* measurement, from the middle of the sternum to the corresponding part of the back, only measured 2 inches instead of 8 or 9 inches!

Occupation likewise modifies the form of the thorax. The clerk who writes many hours at the desk, carries himself differently to the soldier. Coal-miners have stooping chests when they work in districts where the coal seam is thin, and the roof consequently low, as in the north of England. In fact, all trades or occupations which require stooping for many hours together, tend to injure and malform the chest.

Pigeon- or chicken-breast. — This is a malformation quite distinct from any of the above mentioned, always affecting the sternal region in particular. An explanation of this curious disease has attracted the attention of Mr. Shaw, to whom we are indebted for the following remarks.* He noticed the effects produced upon the thorax by violent efforts of breathing in a child with croup. If we watch, says Mr. Shaw, the motions of the thorax in a young patient who is in danger of suffocation from an obstruction in the wind-pipe, we shall perceive that at each inspiration, while the superior ribs and sternum are raised and protruded as in common costal breathing, the lower ribs are, at first, flattened, and then drawn inwards, so as to produce a deep indentation on both sides. The depression is greatest in the line of junction of the ribs with their cartilages; it is as if a band had been tied tightly round the waist, or resembles the indentation near the margin of the chest, often seen in women from tight lacing. The constriction lasts during *inspiration;* in expiration, the ribs by their elasticity flap out and recover their form. That the lower ribs should be drawn inwards in the act of inspiration, diminishing the area of the chest at a time when their natural motion should enlarge it, will be understood by considering the relative conditions of the thorax and the lungs in the laboured respiration which arises from obstruction in the wind-pipe. Under the sense of impending suffocation, the young patient instinctively struggles to enlarge the cavity of the chest to its greatest capacity; but, while that effort is making, the quantity of air that passes into the lungs is very small, because of the obstruction in the larynx or trachea: a portion of air may reach the air-cells at the apex where the bronchial tubes are short, but little or none penetrates so far as the base of the lungs; consequently the lungs are imperfectly dilated. If the child succeed in enlarging the area of the chest in proportion to its powerful efforts, while the lungs were at the same time but partially dilated, it would follow that a vacuum would be produced in the space between the parietes of the thorax and lungs. But owing to the great flexibility of the ribs near the lower margin of the thorax in childhood, the atmospheric pressure overcomes the action of the muscles, and thrusts in the sides so as to preserve the balance of the air within and that without: in common language, the walls of the chest on each side are "sucked" inwards, like the valve in a pair of bellows.

When we look at the general shape of the chest during the continuation of the constriction, we perceive at once a resemblance to the pigeon-breast deformity; there is in both the same protrusion of the sternum, and the same depression of the cartilages on each side.

The question therefore arises, can the deformity have a similar origin to the change in the figure of the chest which is caused by difficult respiration? Dupuytren wrote a memoir upon this form of distortion, and he has shown that difficult respiration and pigeon-breast deformity are frequently associated together, so that he has almost constantly found that patients who are pigeon-breasted have at the same time enlargement of the tonsils; but Dupuytren does not profess to explain why the two complaints should go together. Some years ago Mr. Shaw had under his care a little boy with greatly enlarged tonsils, which were very low down in the throat, owing, as it appeared, to their having got within the grasp of the constrictor muscles of the pharynx. He had constant dyspnœa, and occasional fits of suffocation, in one of which Mr. Shaw performed laryngotomy: on his admission into the hospital, and for several weeks afterwards, it was observed that he had the "pigeon-breast" form of chest; but after his tonsils were excised, and his breathing had been perfectly free for some time, the sternum subsided to its proper level, and the thorax recovered its natural shape. These facts prove that a connection, like cause and effect, exists between obstruction of the air passages and pigeon-breast deformity. It is not necessary that such impediments should be so great as to produce strongly marked symptoms of dyspnœa; for, while the distortion is being produced the child is growing,—both the size and shape of the chest are undergoing a natural change. Mr. Shaw justly considers it quite possible that a cause which may have very slight influence in changing the figure of the thorax, if operating only for a week or a month, will, if continued longer, disturb and modify the process of growth; so that after intervals of half-years or years, a decided effect will be exhibited in the form of the chest. It is not impossible that continued disease in the air passages of children, which may fail to attract much attention, or at least may not be thought capable of producing distortion, may nevertheless gradually and insidiously give rise to the permanent deformity of "pigeon-breast." Mr. Shaw particularly refers to enlargement of the tonsils, attended even with slight inconvenience; to enlargement of the lymphatic

* Deformity of the Chest from Dyspnœa, Oct. 1841. Lond. Med. Gaz. New Series, vol. i. 1842.

glands in the course of the trachea or bronchi; to pressure upon the trachea by the thymus gland, when later than natural in being absorbed, or when hypertrophied; and to morbid thickening of the mucous membrane of the larynx, or of the trachea and bronchi succeeding croup or cynanche pharyngea. We concur with these views upon this subject, the more so as we likewise have noticed the pigeon-breast in children where enlarged tonsils have been present. We must not imagine from this that, where there is dyspnœa, there we shall always find the deformity in question; for difficult breathing may be caused by other circumstances than those which disturb the counter-pressure of the atmosphere in the thorax.

IV. *Dimensions of the thorax.*—The measurement of the thorax may be considered externally and internally; and, what is most remarkable, the one class of measurements may not have any relation to the other class. Moreover, the external measurements bear a certain proportion to the whole frame, whilst the internal do not.

(a) *External measurements of the thorax.*—The external dimensions of the thorax differ much in different men; this is obvious to all. There is the broad-chested and the narrow-chested man. Mr. Brent has calculated, from an extensive number of observations, the following proportions, which we arrange thus:—

TABLE D.—Relation of the External Chest to the Height, measured over the Nipples.

Minimum chest: $\frac{1}{2}$ of the stature — $\frac{1}{61}$ of the stature = circumference of chest.
Medium chest: $\frac{1}{2}$ of the stature + $\frac{1}{15}$ of the stature = circumference of chest.
Maximum chest: $\frac{2}{3}$ of the stature = circumference of chest.

For example, let us suppose a height of 61 inches, as follows,—

Minimum chest: height 61 in., $\frac{1}{2}$ = 30·5 in. — $\frac{1}{61}$ = 29·5 in. circumference of chest.
Medium chest: height 61 in., $\frac{1}{2}$ = 30·5 in. + $\frac{1}{15}$ (= 4·07) = 34·57 in. circumference of chest.
Maximum chest: height 61 in., $\frac{2}{3}$ = 40·7 in. = circumference of chest.

Thus, by taking the most perfectly proportioned chests, either from living figures or from the classical athletæ of ancient sculptures, the following is the result.

TABLE E. — External Thoracic Dimensions, (in three classes according to weight) in relation to the height, obtained from calculation.

MALES: CIRCUMFERENCE OF THORAX.			
Height.	Minimum Weight.	Medium Weight.	Maximum Weight.
Ft. In.	Inches.	Inches.	Inches.
5 0	29$\frac{3}{4}$	34	37$\frac{1}{8}$
5 1	30$\frac{1}{4}$	34$\frac{3}{4}$	37$\frac{3}{4}$
5 2	30$\frac{3}{4}$	35$\frac{1}{4}$	38$\frac{3}{8}$
5 3	31$\frac{1}{4}$	35$\frac{7}{8}$	39
5 4	31$\frac{3}{4}$	36$\frac{3}{4}$	39$\frac{5}{8}$
5 5	32$\frac{1}{4}$	37	40$\frac{1}{4}$
5 6	32$\frac{3}{4}$	37$\frac{1}{2}$	40$\frac{7}{8}$
5 7	33$\frac{1}{4}$	38$\frac{1}{8}$	41$\frac{1}{2}$
5 8	33$\frac{3}{4}$	38$\frac{5}{8}$	42$\frac{1}{8}$
5 9	34$\frac{1}{4}$	39$\frac{1}{4}$	42$\frac{3}{4}$
5 10	34$\frac{5}{8}$	39$\frac{5}{8}$	43$\frac{1}{4}$
5 11	35$\frac{1}{4}$	40$\frac{1}{4}$	44
6 0	35$\frac{5}{8}$	40$\frac{3}{4}$	44$\frac{5}{8}$

From this the minimum chests increase on an average nearly $\frac{4}{8}$ (3·9), the medium chests rather more than $\frac{4}{8}$ (4·2), and the maximum $\frac{5}{8}$ of an inch for every increasing inch of *stature*. We have found from *observation*, upon 1276 cases of all various classes conjoined, a regular arithmetical progression of the thoracic circumference over the nipples in relation to weight.

By the total mean of our observations the chest increases exactly one inch for every 10 lbs. increase of weight, sinking the effect of height, which, however, cannot well be omitted, because, as a general rule, the height increases with the weight.

Mr. Brent has found that twice the breadth of the shoulders equals the circumference of the thorax over the nipples — *i. e.* from point to point, or the caliber of the broadest part of the shoulders. Thus, if the caliber be 18 inches, the thorax will be 36 inches in circumference. Four times the distance between the nipples is equal to the circumference. Four times the antero-posterior diameter is equal to the circumference: therefore the distance between the nipples is equal to the depth from before backwards of the external thorax. At the height of 5 feet 9 inches this antero-posterior diameter varies from 7$\frac{1}{2}$ inch. to 12$\frac{1}{4}$ inches.

(b) *Internal measurement of the thoracic cavity.*—Before entering into details we may observe, that the thoracic cavity is much smaller than we might, perhaps, be led to expect; that the depth from above downwards is, when compared with the body, very shallow. It is, however, capable of enormous dilatation or mobility, even to 100 per cent; 80 per cent is common.

The *absolute* dimensions of the thoracic cavity of *females* are obviously smaller than those of males, because they are altogether of smaller conformation, both in stature and weight; but, *relatively*, the difference is probably little. Although the proportion of some of the diameters may differ, yet that of the total cubic measurements appears not to do so.

A certain rude relation of necessity must exist between the size of a man and the dimensions of his thoracic cavity. A man 7 feet high will have a larger chest than one 5 feet or 6 feet high. But there is no *constant* and uniform relation of the *size* of the chest, either to the height or weight of the body. The *function* of the chest, however, as indicated by the quantity of air which we can expel, is in strict relation to the minute difference of a single inch of stature, or to 10 lbs. of weight. It appears probable that the function of an organ may be exactly relative to the size of the body, increasing or decreasing with it, while the organ itself bears no visible relation of volume either to its own activity or to the dimensions of the body.

The greatest perpendicular depth of the thoracic cavity, nearly corresponds with the greatest lateral measurement; or if the depth be 8·7 the breadth is 9·7, and allowing for the mobility of the base of the thorax, the depth may yet more closely correspond to the breadth. The average perpendicular depth of the female thorax exactly corresponds with the average breadth, being 8·1 inches in both measurements. The greatest antero-posterior diameter in both sexes, *i. e.* from the sternum to the deepest part of the great lateral groove at the angle of the rib, is always less than the greatest lateral breadth, being as 6 to 9 in the male, and as 6 to 8 in the female.

These diameters, however, in no way correspond to the stature. A man, 5 feet 4 inches high, measured from the apex of the chest to the base $10\frac{1}{2}$ inches, whilst a man of 5 feet 10 inches, only measured $7\frac{1}{2}$ inches in the same direction, or the shorter man exceeded the taller by 3 inches in the perpendicular depth of his thoracic cavity:—but the taller man could exceed the shorter by a volume of 77 cubic inches of air at one deep expiration. In fact, the whole of the

Vital capacity - - - - - - - -	205 cub. in.	187 cub. in.

In the males the left apex was highest in 6, the right in 6, and in 2 the summits of the apices were on the same level; in the females, the left apex was highest in 2, and the right in 4.

internal measurements (cubic or diameter) clearly bear no relation to the height or weight of the man, whilst *vital capacity* * does so in an exact ratio.

If we take a cast of the thoracic cavity and view the *base*, it presents the shape of the figures in diagram *fig*. 669. which gives a mean measurement, in the males of forty-six, and in females of thirty-five, superficial inches In the diagram (reduced by scale), we affix the height of each case, and the area in superficial inches of such section.

But the base of the thorax presents another measurement, that of the absolute area of the diaphragm. By the *figs*. 2. and 3., art. DIAPHRAGM, this muscle will be noticed as a large muscle of a vaulted form. C. *fig*. 670. represents a section of a thorax, the measurement of

Fig. 670.

which is forty superficial inches; the figure B, next above, is the diaphragm of the same person spread out, which is extended to 110 square inches, being nearly three times the area of the former figure ; even in this condition the centre is quite free, and not upon the stretch, though the circumference is so. The full measurement is nearly obtained, by slitting up the sides, as shown in figure A. and this condition gives it an increase of twenty-two superficial inches, making altogether 133 square inches ; but even in this condition the entire arched muscle is not perfectly spread out. This was the diaphragm of a man five feet six inches high, with an exceedingly small chest, only twenty-nine inches in external circumference, and whose vital capacity was 188 cubic inches. The section, therefore, of the thorax to the area of the diaphragm is as 40 to 133, or 1 to 3·3. This renders the base of the thorax highly mobile.

There is, perhaps invariably, a *difference in the dimensions of the two sides of the thorax*, in favour of the left side. The least difference which we observed was one cubic inch, but we think there must have been some error in this observation. Passing this over, we may say that the difference between the two sides varies from 10 to 77 cubic inches, and that, in all cases examined by us, the left side was larger than the right. This difference, also, we have found not to bear any relation to sex or stature. One female of 5 feet 4 inches in height had a difference of 77 cubic inches, which exceeds by 10 inches any of the males which we examined, up to 5 feet 10 inches high.

OF THE RESPIRATORY MUSCLES. — There are certain muscles *especially* destined to expand and contract the thoracic cavity, and there are others which act in different degrees as accessories, they may be classed as direct and indirect respiratory muscles.

The *direct* respiratory muscles are, *intercostales externi* and *interni*, *levatores costarum*, *infra costales*, *triangularis sterni*, and the *diaphragm*. The *indirect* respiratory muscles are all those which straighten the spine or aid in fixing the whole body for the thoracic muscles to act from as a fixed point, whilst by their other attachment they elevate or depress the ribs ; these are particularly the muscles of the neck and upper extremities, and those composing the walls of the abdomen. More indirectly still, the muscles of the limbs assist in respiration ; — in difficult respiration, the patient seizes hold of any fixed object, whilst he employs his whole muscular force to assist in inspiration, or, as Boerhaave has expressed it, " scarcely any particle remains in the body which is not more or less concerned in the business of respiration."* The indirect respiratory muscles, in fact, comprise nearly all the muscles of the body ; therefore we shall only notice the direct respiratory muscles. The diaphragm has already been described (art. DIAPHRAGM).

I. *The intercostal muscles* are arranged as two thin laminæ between the ribs ; one lamella is external to the other, hence they are named external and internal. The fibres of each layer are oblique in their direction in reference to the ribs, and each layer has its fibres disposed in a contrary direction to those of the other ; thus they are said to decussate. The twelve ribs form eleven intercostal spaces, consequently there are eleven such decussating lamellæ on each side of the thorax, and twenty-two in all. Their attachments are to the inferior border of one rib, and to the superior

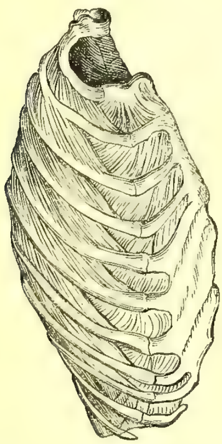
* By "vital capacity" is meant the measure of the mobility of the chest, as more fully explained hereafter. (P. 1056.)

* Prælect. ad Instit. 601. Morgagni. By Alexander, vol. i. p. 357.

border of the next below. They do not accompany each other throughout the entire intercostal space. These muscles, therefore, differ from each other in two ways, in the direction of their fibres, and in the extent of their attachment, for neither set are prolonged throughout the entire length of an intercostal space.

(a) *Intercostales externi.*—These have their fibres running obliquely downwards and *forwards;* they are continued throughout the whole osseous intercostal space, *i. e.* from the tubercles of the ribs, to where the cartilages commence; here they terminate. Haller once noticed these fibres "continued without interruption to the sternum, filling up the intercartilaginous spaces."* A thin aponeurosis is prolonged from the free anterior margin of this layer, up to the sternum. This muscular layer is thicker than the internal layer. *Fig.* 671. represents the anterior extremity of this

Fig. 671.



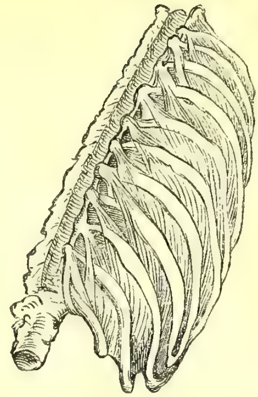
External intercostals. — Anterior view.

layer, where it terminates with the osseous part of the rib, and *fig.* 672. the posterior view, commencing at the vertebræ.

(b) *Intercostales interni.* — These, as their name implies, are internal to the above layer. Their fibres are likewise oblique, and have a contrary direction, downwards and *backwards* crossing the former layer. They commence at the sternum, fill up the intercartilaginous spaces, and *part* of the interosseous spaces, and terminate at the angles of the ribs. *Fig.* 671. represents them commencing at the sternum, and disappearing behind the external layer. *Figs.* 673. and 674. show them for the remainder of their course; in *fig.* 673. they will be seen to terminate short of the vertebral column. A thin aponeurosis is prolonged from their free margin backwards, to the end of the intercostal spaces.

All the intercostal fibres are oblique in their direction, with reference to the spine and sternum. The fibres of one intercostal space differ

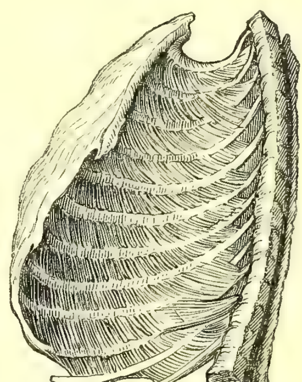
Fig. 672.



External intercostals. — Posterior view.

in their degree of obliquity relatively to those of other intercostal spaces Thus, broadly, it may

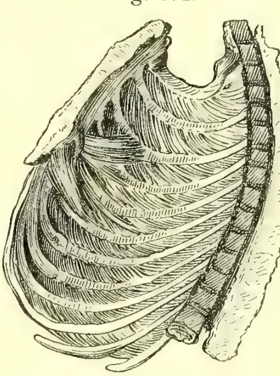
Fig. 673.



Internal intercostals. — Posterior view.

be stated that the external intercostal fibres *increase* in the degree of their obliquity as they

Fig. 674.



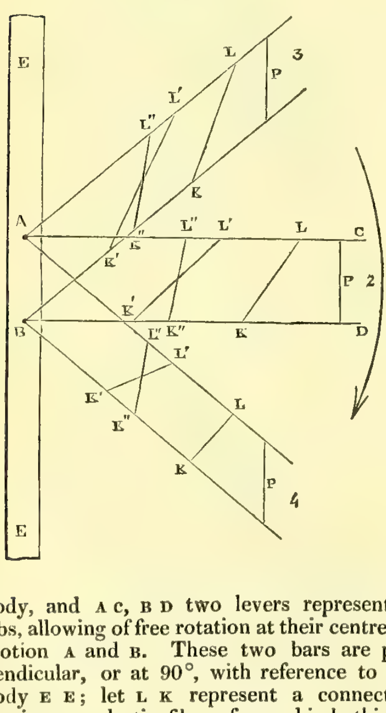
Internal intercostals. — Anterior view.

proceed from the first to the last intercostal space; and that the internal intercostal fibres,

* El. Phys. tom. iii. p. 29.

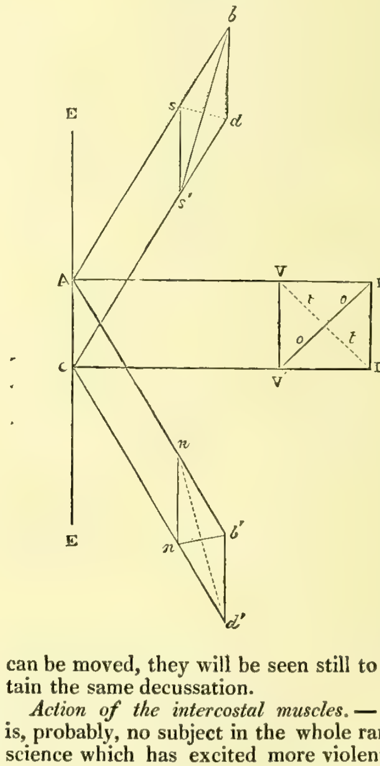
on the contrary, *decrease* in the degree of their obliquity as they proceed in the same direction. Moreover, for the most part the external fibres increase in their obliquity in the *same* intercostal space as you proceed from the vertebræ towards the sternum, and the internal intercostal fibres, on the contrary, increase their obliquity from the sternum towards the vertebræ, therefore they seldom decussate at right angles to each other, or form a perfect cross like the letter X. This is their general relative position at death, but, during life, in every stage of respiration, their degree of obliquity varies. The obliquity of the intercostal fibres should be viewed more with reference to the spine than to the ribs, because we shall show that their action is relative to the spine, and not to the ribs and that they may be perpendicular to two ribs, while they are oblique to the spine, because the ribs are themselves oblique. We have never seen any of the external intercostal fibres perpendicular to a rib, but we may see that arrangement in the internal layer of the lower intercostal spaces (*fig.* 673.). The omission of the relative position of the spine with reference to the obliquity of these muscles has led to many false conclusions as to their action in respiration. Let E E (*fig.* 675.) represent a spine or a rigid

Fig. 675.



body, and A C, B D two levers representing ribs, allowing of free rotation at their centres of motion A and B. These two bars are perpendicular, or at 90°, with reference to the body E E; let L K represent a connecting tension or elastic fibre of any kind, this is oblique with reference to the two bars A C and B D, but move these bars down to the position of P 4, at an angle of 45° to the body E E, and the fibre L K becomes perpendicular to the two bars; now move the bars up to P 3, also at an angle of 45° with E E, and the fibre L K becomes more oblique than at the position P 2. Therefore a tension may change from the *oblique* to the *perpendicular* relatively to the ribs; but it can never so change its relation to the spine. Thus L″ K″ and L′ K′ between the bars at P 3 cross each other, in the same *direction*, but in different *degrees of obliquity;* when the bars are at P 4., they decussate in directions contrary with reference to the bars, but not with reference to the body E E. The position of the ribs is similar to the bars at P 4, therefore the decussation of the intercostal muscles must be viewed with reference to the spine. The intercostal fibres never cross each other like the lines L′K′ and L″K″ (*fig.* 675.), nor can they, by any change of movement, ever assume thatposition ; *i. e.* if they do not decussate in a direction contrary with relation to the spine, in no change of position, throughout the range of a semicircle, can they ever become directly decussating fibres but when they directly cross each other as V D and V′ B (*fig.* 676.) relative to E E, in every other position to which the bars

Fig. 676.



can be moved, they will be seen still to maintain the same decussation.

Action of the intercostal muscles. — There is, probably, no subject in the whole range of science which has excited more violent contention and acrimonious dispute, than that of the action of the intercostal muscles. The illustrious and learned Haller could not enter this field of inquiry without pausing to observe: "Let it be allowed me to deplore among the miseries of human life, that such anger and bitter quarrels should be forced upon us on account of matters wherein we are so little personally concerned."*

Yet, strange to say, Haller opposed with extreme violence his contemporary Hamberger, whose investigations on this subject, though still extant, fell, consequently, into oblivion.

We know not who discovered the two sets of intercostals. There appears to be no account of them prior to Galen, A. D. 131. He observes, "the intercostal muscles help the midriff, that they might draw the chest inward."† Albinus (A. D. 1770) considered that both the internal and external layers "raise the ribs."‡ H. Cooke, a learned compiler of 1651, believed, they "constrained and dilated the chest," — "that the external layers bear down the ribs, and that the internal separate the ribs, so enlarging the thoracic cavity."§ Strange to say, after this Cooke divests these muscles of all thoracic motion whatever.

In 1685 it was the received opinion that the external layer dilated, and that the internal layer contracted the thorax.|| John Alphonso Borelli led the way to a different opinion, which prevailed amongst most physiological writers. He believed, from mathematical reasoning, that "the fibres crossing each other produced only one effect, viz., the drawing of the ribs together," — acting in the diagonal of the decussation. It is curious that he never considered the probability of the two forces acting separately, as other antagonising muscles can do.¶ W. Cheselden believed that both these muscles dilated the thorax, acting as elevators of the ribs, when the 1st rib was fixed by the scaleni and serratus posticus posterior.**

Cooke follows the views of Cheselden and Borelli.†† Benjamin Hoadly takes another view; and, in so doing, illustrates the subject with diagrams, and comes to the conclusion that the external layers elevate, and that the internal depress the ribs; and that their combined action is to arrest the respiratory movement at will. He also says, "*neither* range can by their action push the ribs asunder."‡‡ Winslow agrees with Borelli: presupposing, as usual, that the first rib is fixed.§§

Still the subject continued to be warmly disputed, when Haller published a controversial paper in 1746. In his "*Elements*," he treats the subject at length, siding with those whom he thinks are right, and confirming the same by many direct experiments.* Haller's view is, that the external layers *elevate* the ribs, because their superior attachment is nearer the vertebræ than their inferior one. Franciscus Boissier de Sauvages agrees with him; and the same is held by the majority, yet some doubt it.

His opinion touching the internal layer is, that they likewise act as associates and elevators of the ribs with the external layer, because "their superior attachment is nearer the sternum, and further from that bone in the lower ones;" likewise, that "that portion of the internal layer placed between the bony parts of the ribs, cannot have a different action from that portion placed between the cartilages." Joh. Swammerdam, Francis Bayle, J. Wilhelmus Pauli, Christianus Vater, Francis Nicholls, J. Fredericus Schreiber, differ from this, believing that the internal layers draw down the ribs.

Now follows a sharp antagonist to Haller, viz. Hamberger, whose disputes with Haller we gather from Haller's writings, and not from Hamberger's writings.

Hamberger breaks out with an entirely new view, which excites Haller to controversy.†

Hamberger, says Haller‡, believes that the external intercostal muscles have one action, — that they would raise the sternum: "that the internal layer would depress it." Hamberger makes a machine "to demonstrate, that when the ribs are raised by these muscles their intervals are *dilated*; when depressed, on the contrary, they are diminished." He furthermore gives, as his own discovery, that "the internal intercostals conjoining the osseous portions of the ribs, and that portion which is between the cartilages, will raise them, and are therefore associated in action with the external layer." Hamberger was the first to assign a double action to the same class of muscles: he likewise believed that the whole ribs were lifted simultaneously.§ Haller disputes the validity of Hamberger's experiments, upon the ground of his not considering the relative mobility of the first and second rib; because, says Haller, if the depressing power of the intercostal muscles is to the first rib as 20, the elevating power on the second rib, by reason of the difference of length and mobility, is as 380, nearly nineteen times greater; and the lower rib is to each superior rib, as far as the seventh, more moveable, in the ratio of 109 to 79.|| We cannot see, with Haller, how the ten-
